Void

An Eliminative Ontology of Distinction

For Lara, Lia, and Lukas.

May you always question, and may the questions be beautiful.

Abstract

Begin with nothing. No axioms, no particles, no space, no time—the unmarked state before any distinction has been drawn.

Now ask: what survives? Not what can be built, but what cannot be destroyed. Apply the filter of self-consistency—mechanically, without exception—and trace what remains when every structure that contradicts itself has been annihilated.

The answer is not a model. It is a verdict. A single structure survives the filtration: the complete graph K_4, four vertices bound by six edges—the unique fixpoint that self-consistency cannot reach. The derivation is verified in Agda under the flags --safe and --without-K: no postulates, no external axioms, no appeal to the uniqueness of identity proofs. Nothing enters from outside.

The combinatorial invariants of this structure—vertex count, edge topology, spectral decomposition, Euler characteristic—are not parameters. They are necessities of the derivation. Their numerical values can be compared with independently measured constants of physics, including the fine-structure constant $\alpha^{-1} \approx 137$. That comparison is not part of the derivation; it is the question this work places before the reader.

The chain closes. The book's final theorem proves that any admissible physical record already presupposes a distinction—the first act the void performs upon itself. The starting point cannot be dropped, because it was never assumed. It is what the void already is, the moment it is examined.

A derivation so compressed touches many disciplines at once—logic, combinatorics, group theory, spectral analysis, physics—and every one of them was built by someone else. The debts are large because the chain is long.

Debts

None of the ideas in this work are new. The derivation is a single thread; what follows names the hands that spun it.

The starting point—that a distinction, not a thing, is the irreducible atom of form—belongs to George Spencer-Brown. The conviction that this is not metaphor but physics, that reality reduces to yes-or-no at every point, is John Archibald Wheeler's *it from bit*.

That such a claim can be made rigorous at all is owed to the constructivists. Brouwer insisted that existence demands a witness. Heyting gave that demand algebraic form. Curry and Howard

revealed that proofs and programs are the same act. Per Martin-Löf forged these insights into a type theory strong enough to carry mathematics, and Voevodsky showed what must be given up—axiom K, uniqueness of identity proofs—if homotopy is to be taken seriously. Every line of this work executes inside those constraints.

The combinatorial backbone has older roots. Euler first counted vertices, edges, and faces as a single invariant. Cayley classified graphs by their symmetries. Birkhoff established when a representation is canonical—when structure admits exactly one normal form. These are the tools that force K_4, and only K_4, out of the filtration.

That the survivor carries physical content is owed to the tradition of spectral analysis: Fourier decomposed signals into modes, Laplace gave the operator its name, Hilbert made the space precise. In this work, the Laplacian of K_4 yields a spectrum—$\{0, 4, 4, 4\}$—that was not chosen but inherited.

What connects spectrum to measurement is symmetry, and symmetry has its own lineage. Galois revealed that solvability is a property of the group, not the equation. Noether proved that every continuous symmetry produces a conserved quantity. Curie showed that what breaks the symmetry is as real as what preserves it. Here, the automorphism group $\mathrm{Aut}(K_4) \cong S_4$ is the arbiter: only quantities invariant under it qualify as observables.

The physical endgame was prepared by those who first extracted constants from constraint. Sommerfeld isolated α. Dirac demanded that the electron obey logic so strict it predicted the positron. Feynman showed that all paths contribute—and that consistency among them is the only filter. Planck proved that nature herself quantizes. The claim that $\alpha^{-1} = 137$ falls out of combinatorial necessity, not measurement, is placed before a tradition that earned the right to test it.

The categorical perspective—that structure is characterized not by what it *is* but by the maps it *admits*—descends from Lawvere and the tradition of Tarski, where fixpoints are not found but forced by the architecture of the logic itself.

What this work contributes is not a new insight. It is a tool applied: the Agda type checker, which enforces logical consistency without exception, turned loose on the question these people raised from different directions. If the result has any value, it is because the filter is trustworthy—not because the author is clever.

Navigator

Machine-verified in Agda (--safe --without-K*, zero postulates, ∼27,000 lines). If you are reading this to evaluate the formal claims rather than the narrative, begin here. Every entry in the tables below is a theorem at the line reference given; every numerical value is a* refl *closed by the Agda type checker.*

Formally Verified Numerical Claims

No value in the following table was fitted or adjusted. Each is the output of a definitional equality checked by Agda. Deviations from measurement are stated honestly; where they exceed 1% an explicit epistemic flag appears in the referenced section.

Quantity	Derived value	Measured	Section
α^{-1} (exact, tree-level)	$V^d\chi + d^2 = 128 + 9 = 137$	$137.036\ldots$	§51
α^{-1} (corrected, $+11/306$)	$137.0359\ldots$	$137.03599\ldots$	§51
Proton/electron (corrected, $+11/72$)	$1836.15\overline{27}$	1836.15267	§51
Muon/electron (corrected, $-16/69$)	$206.7681\ldots$	206.7683	§51
Tau/muon (corrected, $-28/153$)	$16.8170\ldots$	16.8170	§51
Weinberg angle (corrected, $-11/576$)	$0.2309\ldots$	0.2312	§51
Baryon fraction (corrected, $-1/102$)	$8/51 \approx 0.1569$	0.157	§51

Precisions (relative error): α^{-1}: 3.8×10^{-7}; proton: 6×10^{-7}; muon: 8×10^{-7}; tau/muon: 1.9×10^{-6}; Weinberg: 0.13%; baryon: 0.1%.

Formally Verified Structural Claims

Claim	Section
Distinction is the unique minimal two-class type (Two-distinction)	§4
Exactly 4 endomorphisms on the two-class carrier (EndoCase, 4 constructors)	§4
All 6 pairs are mutually distinct (6 absurdity witnesses $\lambda\,()$)	§4
K_4 is the unique forced graph (law13-1-presentation-iso)	§17
Loop numerator 11 forced (8 candidates $\to$ 1 survivor)	§51
$c = \hbar = G = 1$ forced; zero free parameters (NormalizedScaleChoice)	§50
K_4 physical record is a singleton—no rival survives	§45
Any admissible physical record presupposes a distinction (loop closes)	§51

Reading Order

For the formalism reviewer: §4 (four-case classification) → §17 (K_4 uniqueness) → §45 (singleton record).

For the physics reviewer: §51 ($\alpha^{-1} = 137$) → §51 (numerator 11 forced) → the correction sections in the table above.

For the philosopher: §50 (measurement presupposes distinction) → §51 (the loop closes).

Scope of the claim. The tree-level values $\alpha^{-1} = 137$, proton $= 1836$, and muon $= 207$ are exact refl equalities derivable from the K_4 invariants $(V, E, d, \chi, \kappa) = (4, 6, 3, 2, 8)$ with no free parameters. Corrections reduce residuals to 10^{-6}–10^{-7} using the same invariants via coprimality and spinor-saturation filters, each proved by absurdity witnesses. Whether these matches are deep or coincidental is an open question, flagged explicitly at §51. The derivation itself is verified; the interpretation is offered for scrutiny.

Chapter 1

Introduction

Three Questions, One Filter

The void is the unmarked state. It precedes axioms, precedes distinction, precedes even the question of whether anything exists. But the void is not stable—because any system capable of examining itself already distinguishes examination from non-examination. The unmarked state, the instant it is interrogated, marks itself.

Three disciplines have arrived at this boundary independently.

Mathematics asks: which structures are consistent? Physics asks: which laws survive observation? Logic asks: which statements can be decided at all?

Different languages, different departments, different journals—and yet, when pushed far enough, all three converge on the same mechanism: an internal filter that none of them chose. Mathematics eliminates structures that contradict themselves. Physics eliminates theories that violate observed invariants. Logic eliminates propositions that cannot be assigned a truth value without inconsistency.

What cannot stand under its own requirements, falls. The stages differ. The verdict is identical.

If the filter is the same everywhere, could the survivor also be the same?

Elimination as Method

The standard approach in formal work is constructive: posit axioms, define structures, prove theorems, build upward. The direction is from assumption to consequence.

This work begins from the opposite end—the void.

Nothing is assumed. Nothing is postulated. The starting point is not a structure but the absence of structure, and then a relentless filter is applied. At every stage, the question is the same: which structures survive their own consistency requirements? Those that do not are annihilated. Those that do, persist—not by choice, but because elimination could not reach them.

This is not a new idea. It is how logic has always worked. But the full consequences of applying this filter mechanically, from the ground up, without exception, have not been traced

before. This book traces them.

The Tool: Agda as Executioner

A filter is only as trustworthy as its enforcement. Human reasoning is fallible: we overlook edge cases, confuse sufficiency with necessity, and mistake intuition for proof. This is why every step in this work is formalized and verified in Agda, a dependently typed proof assistant.

Agda does not care about elegance or plausibility. It checks one thing: does this term have the type it claims to have? If yes, the step stands. If no, it is rejected. There is no override, no escape hatch.

The compiler flags used in this work—`--safe` and `--without-K`—further restrict the environment. No external axioms can be assumed. No postulates can be introduced. No appeal to the uniqueness of identity proofs is permitted. The system is locked into the narrowest possible corridor of logical consistency, and then forced to walk.

What Happens Here

When the proofs become detailed, the global line of force is easy to lose from view. The argument itself has a single irreversible spine:

$$D_0 \longrightarrow \text{minimal logical infrastructure} \longrightarrow \text{classification} \longrightarrow \text{drift and reachability}$$
$$\longrightarrow \text{presentation and fixpoint} \longrightarrow K_4 \longrightarrow \text{arithmetic and spectral invariants} \longrightarrow \text{physics record} \longrightarrow D_0.$$

The spine does not branch—and it does not dead-end. The book's final theorem closes the loop: any admissible physical record already presupposes D_0. The chain is not an open arrow; it is a closed constraint.

The Elimination Protocol

Before entering the proofs, the reader deserves a compact ledger of the entire eliminative chain. At every step below, the column on the right names the alternatives that were tested and destroyed. K_4 is what remains after every row has been executed. Nothing in this list was chosen; everything was forced by the failure of its rivals.

#	Survivor	Why it survives	What was eliminated
1	Distinction (D_0)	The bare act of separating ℓ from r. Any formal system that cannot distinguish true from false is vacuous. Uniquely among all rows: denying D_0 is itself an act of distinguishing, so its negation is self-refuting.	Vacuous carriers, carriers without boundary witnesses, carriers where $\ell = r$.
2	Two-class coverage	Every element of the carrier equals ℓ or r. No unclassified residue is possible.	Carriers with hidden elements, partial classifications, carriers with > 2 equivalence classes.
3	Four endomorphisms	Coverage forces $\lvert\mathrm{End}(S)\rvert = 2 \times 2 = 4$. Each case is mutually distinct.	K_1 (1 vertex — cannot host 4 distinct maps), K_2 (2 vertices — collapses constant maps), K_3 (3 vertices — one case always orphaned).
4	Drift acyclicity	Applying classification to classification produces a level tower. The reachability relation on that tower is well-founded.	Cyclic level structures, infinite descending chains, non-well-founded hierarchies.
5	Presentation fixpoint	Every reachability witness reduces to a canonical finite form. The observable that measures proofs factors through a unique base.	Non-canonical representations, observables that depend on proof-internal choices, redundant witnesses.
6	K_4	The complete graph on four vertices is the unique fixpoint of the filter. No proper subgraph survives all five constraints above.	Every proper subgraph of K_4, every supergraph, every non-complete topology on four vertices.
7	Derived arithmetic	K_4 forces counting (naturals), orientation (integers), spectral ratios (rationals), limit closure (reals).	Number systems not grounded in K_4 structure, algebraic laws that contradict the spectral data.
8	Physics record	The combinatorial invariants of K_4 ($V = 4$, $E = 6$, $d = 3$, $\chi = 2$, $\mathrm{Spec} = \{0, 4, 4, 4\}$) yield $\alpha^{-1} = 137$ by evaluation (§51). No free parameter.	Any alternative constant that would require a different graph or a tunable parameter.

The protocol is the backbone of the argument. If any single row could be replaced by a genuine alternative—if, at any step, the eliminated rival could survive instead—then the derivation would branch and the uniqueness claim would fail. The remainder of the book is the proof that no such branch exists. Uniqueness is not asserted; it is proved twice over: once for the graph (Part IV establishes K_4 as the sole fixpoint), and once for the physical representation (Chapter 45 proves that any two admissible physics records must agree on all fields).

This book proceeds in six parts. The first four derive K_4 through elimination. The fifth builds the arithmetic its structure makes necessary. The sixth computes the physical constants its invariants determine.

Part I (Foundation) establishes the minimal infrastructure that any consistent formal system must carry: equality, pairing, negation, decidability, and the natural numbers. None is introduced by fiat. Each is shown to be the unique survivor when the alternative is tested for internal consistency and fails.

Part II (Drift and Reachability) discovers what happens when classification is applied to classification itself. Each level of the type hierarchy is forced by the unclassified residue of the level below it. The reach proofs in this part track that ascent through the tower.

Part III (Heteromorphisms and Presentation) extends the classification to maps between two distinct carriers—not just within one. The same four cases survive. The presentation theorems then reduce every reachability fact to a finite canonical witness.

Part IV (Observables and Fixpoint) identifies which quantities that functionals can measure on proofs are actually determined by structure rather than proof-choice. The answer is a fixpoint: every admissible observable factors through a unique base computation. The K_4 graph—four vertices, six edges, complete—is the result of applying this filter to everything derived so far.

Part V (Derived Arithmetic) builds the number systems that K_4's structure demands. Integers arise from orientation. Rationals arise from spectral ratios. Reals close the Cauchy gaps. Measurement, scaling, and distance laws follow—all without any postulate beyond what Parts I through IV established.

Part VI (Physics from K_4) assembles the invariants into a verified computation record. The vertex count, edge structure, Euler characteristic, and spectral decomposition of K_4 produce numerical values that can then be compared with independently measured constants of physics. The computation is theorem; the comparison is interpretation. The former is proved, machine-verified, and offered first. The latter is left open to the reader's evaluation.

The chapters do not wander away from this chain. They only slow down at different points in order to verify that no weaker alternative survives. The reader is invited to verify every claim. The source of this book is itself the proof: a literate Agda file where prose and machine-checked code are one and the same document.

Two Paths, One Verdict

A companion volume, *Form*, derives K_4 by the opposite method: not elimination but construction. Starting from the mark D_0 as a single inhabited type, *Form* builds upward—witness, cut, Bool, natural numbers, integers, rationals, reals—until the complete graph appears as the unique structure the genesis sequence forces.

The two proof chains are independent. They share no lemmas, no intermediate definitions, no common code. *Void* begins with abstract type-theoretic infrastructure—propositional equality, universe lifting, contractibility, distinct-pair classification—and then filters. *Form* begins

with concrete inhabited types—D_0, D_1, D_2—and then constructs. The Agda modules do not import from each other.

The divergence extends deeper than subject matter: it reaches the proof machinery itself. The eliminative method asks, at every branching point, "can this alternative be ruled out?" That question is inherently propositional—it demands a witness of type Dec $(x \equiv y)$, a proof term that the type-checker must carry and reduce. As propositional chains grow, Agda's definitional reduction engine is forced to unfold long multiplication and Laplacian entries; the opaque keyword becomes necessary to keep the checker's memory bounded. None of this is a design decision—it is the cost of elimination.

The constructive method asks a different question: "what does this compute to?" That question is inherently computational—it demands a function of type $X \to X \to$ Bool, a decision procedure that pattern-matches to true or false and then forgets why. The reduction chains are shorter because the result is a bit, not a proof tree. Integer equality is checked by setoid comparison ($\simeq_{\mathbb{Z}}$), not by propositional unfolding. No opaque blocks are needed because the computational load never accumulates.

The method forces the machinery. An eliminative proof cannot use Bool decisions without losing the proof terms it needs for later elimination. A constructive proof cannot use propositional witnesses without carrying reduction weight it never discharges. Each path is locked into its own technology—not by preference, but by the logical grammar of its central verb.

This independence is not an accident. It is a consequence of the claim itself. If K_4 is truly the unique fixpoint of self-consistency, then it must be reachable from any direction. A result that can only be reached by one proof strategy is a result that depends on that strategy. A result that survives both elimination and construction depends on neither—it depends on the structure alone.

The two volumes converge on the same invariants: $(V, E, d, \chi, \kappa) = (4, 6, 3, 2, 8)$, the same Laplacian spectrum $\{0, 4, 4, 4\}$, the same derived constants, the same closed loop from D_0 back to D_0. That two independent formal developments, verified by the same compiler under the same flags, arrive at the same terminus is itself evidence—not proof, but evidence—that what they find is not an artifact of how they looked.

The reader who has access to both volumes may verify this convergence directly. The reader who has only this one loses nothing: the eliminative derivation is self-contained.

How To Read This Book

This document can be entered from more than one side.

For the reader following the main argument: read the Abstract, this Introduction, the opening paragraphs of each Part, *Graph Presentation*, *An Unexpected Correspondence*, *K_4 Physics Constants Layer*, and the Conclusion. That path carries the global claim from distinction to K_4 to the physics record without demanding that every intermediate proof be read in full on the first pass.

For the reader testing the formal necessity: follow the code blocks and their immediate narrative wrappers. The prose states what pressure is being applied; the Agda code shows exactly which constructions survive it.

For the reader testing the physics claim first: begin with *Graph Presentation*, then *An Unexpected Correspondence*, then the openings of *Derived Arithmetic* and *Physics from* K_4, and only then descend into the intermediate derivations as needed. The point is not to delay the claim, but to make clear which earlier chapters each later computation depends on.

What begins now is the first irreversible pressure test. The question is not whether something can be pulled from the void—it is whether the void can remain unmarked at all. If it can, nothing follows. If it cannot, then what the void already contains is not a choice but a necessity—and the derivation is a sentence the void passes on itself.

Part I

Foundation

Chapter 2

The Foundation of Necessity

The void must be examined—but the act of examination itself must first be constrained. This is the first step, and perhaps the most counterintuitive: before a single distinction can be drawn, every escape route that would make the result dependent on human choice must be sealed. The doors close before the investigation begins.

Consider what happens if any door remains open. A formal system that permits unproven axioms—postulates accepted on faith—gains arbitrary degrees of freedom. Any structure derived from such a system inherits those degrees of freedom. The results would depend on which postulates a human happened to choose, not on what the void demands. So the first door closes: the Agda flag --safe forbids all postulates. Nothing enters this system that is not constructed from within.

The second door concerns identity. In many formal systems, it is taken for granted that all proofs of the same equality are themselves identical—a principle known as Axiom K. This sounds harmless. But it imposes a hidden constraint: it flattens the space of proofs into a single layer. Higher-dimensional structure—where the *way* two things are equal matters, not just *that* they are—is silently collapsed before it can be examined. Since the investigation must remain open to relational complexity at every level, this premature flattening is unacceptable. The flag --without-K prevents it.

The third door concerns self-reference. Without universe stratification, a type could contain itself as a member—an act that immediately produces paradox (Russell's paradox being the most famous instance). Agda's hierarchy of universe levels (Level, Set_ω) prevents this by ensuring that every type lives strictly below the level that quantifies over it. No type can swallow itself.

Three constraints—no postulates, no identity collapse, no self-reference—and none is a design choice. They are the minimal conditions under which a formal system can interrogate the void without contradiction. The module opens under these restrictions.

```
-- § Strict Environment Constraint: No axioms, no postulates, no Axiom K.
module Void where

-- § Stratification primitives are forced to prevent self-reference paradoxes.
open import Agda.Primitive using (Level; lzero; lsuc; _⊔_; Setω)
```

Propositional Equality

With every door sealed, the first question is immediate: when are two things the same?

This is not a philosophical musing. Without a stable notion of equality, no proof can refer to a previous result. No substitution can be performed. No structure can be recognized across contexts. A system without equality is a system where nothing follows from anything—where every statement is an island. That is not logic. That is noise.

So equality must exist. But what is the minimal form it can take? The answer is surprisingly tight. A single constructor suffices: refl, which states that a thing is equal to itself. Nothing more is assumed. From this one fact, the entire machinery of equality—symmetry, transitivity, congruence, substitution—follows by elimination. Not as additional axioms, but as the only functions the type checker will accept given the structure of refl. Try to define symmetry any other way, and Agda rejects it. There is exactly one implementation that typechecks.

```
-- § Propositional equality: the identity type with unique constructor refl.
infix 4 _≡_

data _≡_ {ℓ : Level} {A : Set ℓ} (x : A) : A → Set ℓ where
 refl : x ≡ x
{-# BUILTIN EQUALITY _≡_ #-}

-- § Symmetry is forced by elimination on refl.

cong f refl = refl

-- § Substitution: transport along an equality proof.
subst : {ℓ₁ ℓ₂ : Level} {A : Set ℓ₁} (P : A → Set ℓ₂) {x y : A} → x ≡ y → P x → P y
subst P refl px = px
```

Universe Lifting

The stratification we imposed in the previous section—universe levels that prevent self-reference—creates an immediate practical problem. A proof living at one level cannot directly interact with a proof living at another. The levels are sealed compartments. Without a controlled passage between them, the system would fragment into isolated strata that cannot communicate.

The passage must satisfy a strict requirement: moving a witness up to a higher level and back down again must return exactly the original witness, unchanged. If the round trip alters anything—introduces noise, loses information, or shifts meaning—then cross-level reasoning becomes unreliable.

Lift is the unique structure satisfying this constraint. It wraps a value and places it one level higher. lower unwraps it. The injectivity lemma that follows immediately proves that no

information is lost: if two lifted values are equal, the originals were already equal. This is not a convenience—it is the proof that the elevator is faithful.

```
-- § Lift embeds a type into the next universe level.
data Lift {ℓ : Level} (A : Set ℓ) : Set (lsuc ℓ) where
 lift : A → Lift A

-- § Lower extracts the embedded value.
lower : {ℓ : Level} {A : Set ℓ} → Lift A → A
lower (lift x) = x

-- § Lift is injective by construction.
lift-injective : {ℓ : Level} {A : Set ℓ} {x y : A} → lift x ≡ lift y → x ≡ y
lift-injective refl = refl
```

Universe-Polymorphic Equality

There is a ceiling in Agda's universe hierarchy: Set_ω, the level that sits above all numbered levels. Statements that quantify over all universe levels—and such statements are unavoidable later—live here.

But the equality type (_≡_) was defined at a specific, bounded level. It cannot operate at Set_ω. This is not a limitation that can be worked around; it is a hard type error. If the gap remains open, then the highest level of the system—the level where the most general statements live—has no notion of identity. Proofs at that level could not be compared, composed, or transported. The top would be lawless.

The solution is forced: replicate the identity type at Set_ω. The replica, _≡ω_, has the same single constructor (reflω) and the same derived operations. It is not a second identity type by choice—it is the only way to extend the guarantees of the lower levels to the ceiling without breaking the stratification that keeps the system sound.

```
-- § Universe-polymorphic equality at Setω.
infix 4 _≡ω_

data _≡ω_ {A : Setω} (x : A) : A → Setω where

congω f reflω = reflω

-- § Substitution at Setω.
substω : {A : Setω} (P : A → Setω) {x y : A} → x ≡ω y → P x → P y
substω P reflω px = px
```

Products and Dependent Pairs

So far, every structure holds a single piece of information. But the moment a statement like "there exists an element with a certain property" must be expressed, two things must be held at once: the element and the proof of its property. Without a way to bundle these together, existential statements are inexpressible. The system can talk about individual objects but cannot witness claims about them.

The product type (A × B) is the simplest response: it holds two independent values side by side. But the more consequential structure is the dependent pair (Σ A B), where the type of the second component depends on the value of the first. This is what makes it possible to say "there exists an a in A such that $B(a)$ holds"—the a and its proof travel together as a single witness. Without dependent pairs, the gap between "for all" and "there exists" cannot be bridged, and half of logic collapses.

```
-- § Non-dependent product of two types.
infixr 3 _×_

record _×_ (A B : Set) : Set where
 constructor _,_
 field
  fst : A
  snd : B

-- § Dependent pair: the type of witnesses.
record Σ (A : Set) (B : A → Set) : Set where
 constructor _,_
 field
  fst : A
  snd : B fst

open Σ public
```

Absurdity and Negation

If the filter we described in the introduction is to have any teeth, it must be possible to express that something *cannot* exist. A system that can only affirm—never deny—has no elimination power. It accepts everything. And a system that accepts everything proves nothing.

The empty type (⊥) is the formal expression of impossibility: a type with no constructors, and therefore no inhabitants. If you somehow hold a value of type ⊥, you have a contradiction—and from a contradiction, anything follows. This is ⊥-elim, the principle of *ex falso quodlibet*: from the impossible, derive whatever you wish.

Negation falls out immediately. To say "A is false" is to say "A leads to a contradiction"—formally, $\neg A$ is the function type $A \to \bot$. No additional negation primitive is needed. Double negation and inequality are then derived forms, not new axioms.

```
-- § The empty type: no constructors, no inhabitants.
data ⊥ : Set where
```

```
-- § Ex falso: the empty type eliminates into any type.
⊥-elim : {ℓ : Level} {A : Set ℓ} → ⊥ → A
⊥-elim ()

-- § Negation: the unique map into absurdity.
¬_ : {ℓ : Level} → Set ℓ → Set ℓ
¬ A = A → ⊥

-- § Double negation.
¬¬_ : {ℓ : Level} → Set ℓ → Set ℓ
¬¬ A = ¬ (¬ A)

-- § Inequality: negation of propositional equality.
infix 2 _≢_
_≢_ : {ℓ : Level} {A : Set ℓ} → A → A → Set ℓ
x ≢ y = ¬ (x ≡ y)
```

Disjoint Union

Pairs express "both A and B." But logic also requires "either A or B"—and it requires knowing *which one*. An untagged alternative—where the two cases are merged without a label—destroys the ability to distinguish them. Case analysis becomes impossible.

The disjoint union (A ⊎ B) solves this by tagging each side: inj_1 marks a witness from the left, inj_2 from the right. Pattern matching can then always determine which case holds. The Set_ω variant (_⊎ω_) extends this to the top universe level, for the same reason we extended equality: every level must carry the full logical vocabulary, or the system has blind spots.

```
-- § Disjoint union (coproduct) of two types.
infixr 2 _⊎_

data _⊎_ {ℓ : Level} (A B : Set ℓ) : Set ℓ where
 inj₁ : A → A ⊎ B
 inj₂ : B → A ⊎ B

-- § Disjoint union at Setω.
infixr 2 _⊎ω_

data _⊎ω_ (A B : Setω) : Setω where
 inj₁ω : A → A ⊎ω B
 inj₂ω : B → A ⊎ω B
```

Ontological Primitives

Before the first distinction can be drawn—the primordial cut between "is" and "is not"—the system must be precise about what it means for a type to be interesting enough to cut at all.

A type that contains only one element, where every inhabitant is provably equal to every other, is *contractible*. It has no internal structure. Drawing a distinction within it is meaningless—there is nothing to separate.

At the other extreme, a type that contains at least two provably *different* inhabitants has a genuine internal boundary. This is the minimal precondition for distinction: you cannot cut what has no parts.

These three predicates—contractibility, the existence of a distinct pair, and non-triviality—are the vocabulary the system needs before the first distinction can even be *stated*. They are not deep theorems. They are the definitions without which the question "can this type be cut?" has no formal meaning.

```
-- § Contractibility: a single center absorbs all inhabitants.
isContr : Set → Set
isContr A = Σ A (λ c → (x : A) → c ≡ x)

-- § A type has a distinct pair if two inhabitants are provably unequal.
HasDistinctPair : Set → Set
HasDistinctPair A = Σ A (λ a → Σ A (λ b → a ≠ b))

-- § Non-triviality: the type is not contractible.
NonTrivial : Set → Set
NonTrivial A = ¬ (isContr A)
```

The Distinction Record

What, then, is a distinction? Not philosophically—formally. If we strip away every detail that is not logically essential, what survives?

A carrier type. Two witnesses in that carrier. A proof that the witnesses are not equal. And a coverage guarantee that every element of the carrier falls into one of these two classes. Nothing less will do: remove any one of these four components and the structure either collapses to triviality or loses the ability to separate. Nothing more is needed: any additional field would be a free parameter—eliminable by the filter we have committed to.

The coverage field in particular admits no weakening. Replacing it with a partial classifier—one that covers only some elements—would leave unclassified witnesses outside any predicate proof. Replacing it with a three-class or richer cover would introduce a third boundary point, making the carrier no longer two-class and the word "distinction" no longer applicable. Two classes is not a choice; it is the exact content the word demands.

The record that follows is not a chosen definition. It is the minimal data that the word "distinction" requires in order to mean anything at all.

```
-- § The first distinction: carrier, boundary points, separation, and coverage.
record Distinction : Set1 where

  r     : S
  ℓ≠r : ℓ ≠ r
  cover : (x : S) → (x ≡ ℓ) ⊎ (x ≡ r)

open Distinction public
```

Chapter 3

Non-Vacuity

The record $\mathrm{Distinction}$ now exists as a type. But types can be empty. If no inhabitant of this type can be constructed—if no actual distinction exists—then every law we derive from it holds vacuously. "For all distinctions d, $P(d)$" is trivially true when there are no distinctions. The entire formal apparatus would prove everything and say nothing.

This is the empty-ontology loophole, and it must be closed before any subsequent reasoning has force. It is closed from both ends: the opening law blocks the vacuous path forward, and the book's closing theorem confirms the loop from the other direction—any inhabitant of the physical record already contains a distinction. The loophole has no exit.

Under --safe, we cannot simply postulate that a distinction exists. But we can demand something weaker and logically sufficient: that the assumption of *no* distinction leads to contradiction. This is double-negation stability—$\neg\neg$ *Distinction*—the weakest assertion that still blocks the vacuous path. It does not hand us a concrete distinction. It forbids us from assuming there is none.

This opening law is deliberately weak. The constructive proof that $\mathrm{Distinction}$ is inhabited arrives in Chapter 5, where $\mathrm{Two\text{-}distinction}$ produces a parameterless witness with no assumptions at all. A second, independent route emerges from measurement (Chapter 50): any binary measurement already carries a distinction kernel in its outcome space. The $\neg\neg$ form stated here is therefore not the strongest available result—it is the weakest barrier that suffices to block vacuity at the earliest possible point in the chain.

A natural objection asks for something stronger still: a proof that *existence itself* requires distinction—that every inhabited type already contains a two-element substructure. In type theory, this claim is simply false. The unit type $\top$ is inhabited by a single element tt, carries no two distinct members, and yet exists without contradiction. The proposition $\forall\,(A : \mathit{Set}).\ A \to \mathit{Distinction}$ is refuted by $A = \top$. Any argument that proceeds from "an object exists without distinction" to "therefore no identity, no reference, no existence claim is possible" collapses at the first step: $\mathrm{tt} \equiv \mathrm{tt}$ is refl, identity is trivial, and reference is unproblematic—all without distinction.

The chain does not need this false theorem. It needs something both weaker and more direct: that $\mathrm{Distinction}$ is freely available as a parameterless construction. $\mathrm{Two\text{-}distinction}$ provides

exactly that. No premise is consumed. No prior existence claim is imported. The type data Two = L | R is definable in every consistent type theory—with or without the axiom of choice, with or without univalence, classically or intuitionistically. Whoever accepts a type theory at all already has D_0.

```
-- § Non-vacuity demands that Distinction cannot be refuted.
record NonVacuityLaw : Set1 where
 field
  nonvacuity : ¬¬ Distinction

open NonVacuityLaw public
```

Law 0.0: Distinction Is Irrefutable

The first law is the simplest and the most important. If ¬ *Distinction* were admissible—if we could consistently deny the existence of any distinction—then every law of the form "for all distinctions d..." would be vacuously true. No elimination would occur. No structure would be forced. The entire investigation would be an elaborate tautology about nothing. Double-negation irrefutability is the minimum witness of existence that prevents this collapse.

```
-- § Law 0.0: Distinction is irrefutable.
law0-0-nonvacuity : (nv : NonVacuityLaw) → ¬¬ Distinction
law0-0-nonvacuity = nonvacuity
```

Law 0.1: Non-Vacuity Is Non-Eliminability

The non-vacuity law says exactly the same thing in its sharpest form: distinction cannot be eliminated. The negation of distinction is itself refutable. This is not a constructive existence claim—we do not hold a distinction in our hands—but it is enough to guarantee that every subsequent argument has a non-trivial domain.

```
-- § Law 0.1: NonVacuityLaw is non-eliminability of Distinction.
law0-1-nonvacuity-is-non-eliminability :
 NonVacuityLaw → ¬ (¬ Distinction)
law0-1-nonvacuity-is-non-eliminability = nonvacuity
```

Law 0.2: Distinction Carrier Is Inhabited

Once a distinction exists, its carrier cannot be empty. The boundary witness ℓ is already part of the record—it *is* a member of the carrier by construction. This is not a theorem that requires proof; it is an immediate consequence of what "distinction" means. An empty carrier would have no witnesses, and a structure with no witnesses is no distinction at all.

```
-- § Law 0.2: Distinction carrier is inhabited.
law0-2-inhabited : (d : Distinction) → S d
law0-2-inhabited d = ℓ d
```

Law 0.3: Distinction Carrier Has A Distinct Pair

The carrier does not merely contain an element—it contains two elements that are provably not equal. The boundary witnesses ℓ and r, together with the separation proof $\ell \neq r$, hand us a distinct pair directly from the record. No carrier with fewer than two distinguishable elements can support a distinction.

```
– § Law 0.3: Distinction carrier has a distinct pair.
law0-3-has-distinct-pair : (d : Distinction) → HasDistinctPair (S d)
law0-3-has-distinct-pair d = (ℓ d , (r d , ℓ≠r d))
```

Law 0.4: Distinction Carrier Is Non-Contractible

A contractible type is one where every element is provably equal to a single center point. If the carrier were contractible, then ℓ and r would both collapse to that center—and therefore to each other. But $\ell \neq r$. Contradiction. Contractibility is dead on arrival.

```
– § Law 0.4: Distinction carrier is non-contractible.
law0-4-not-contractible : (d : Distinction) → NonTrivial (S d)
law0-4-not-contractible d (c , collapse) =
 ℓ≠r d (trans (sym (collapse (ℓ d))) (collapse (r d)))
```

Law 0.5: Distinct Pair Forces Non-Contractibility

This is the general principle behind the previous law, freed from the specific context of distinction. Whenever *any* type carries a pair of elements known to be unequal, that type cannot be contractible. The center of contraction would identify the pair, contradicting their separation. The proof is identical in structure: transport through the center, arrive at equality, invoke the separation witness.

```
– § Law 0.5: Distinct pair forces non-contractibility.
law0-5-distinct-pair-forces-nontrivial :
 {A : Set} → HasDistinctPair A → NonTrivial A
law0-5-distinct-pair-forces-nontrivial (a , (b , a≠b)) (c , collapse) =
 a≠b (trans (sym (collapse a)) (collapse b))
```

Law 0.6: Distinction Is Reconstructible From Its Data

If you have a type, two elements of that type, a proof of their inequality, and a coverage function—then you have a distinction. There is no fifth ingredient, no hidden requirement, no gap between "having all the data" and "having the record." The record is exactly its fields, nothing more. This is what makes the formalization honest: the definition conceals no implicit structure.

```
– § Law 0.6: Distinction is reconstructible from its data.
fromDistinctCovered :
 {S₀ : Set} (a b : S₀) →
 a ≠ b →
```

```
((x : S₀) → (x ≡ a) ⊎ (x ≡ b)) →
 Distinction
fromDistinctCovered {S₀} a b a≠b cov = record
 { S = S₀ ; ℓ = a ; r = b ; ℓ≠r = a≠b ; cover = cov }

law0-6-reconstruction :
 {S₀ : Set} (a b : S₀) →
 (a≠b : a ≠ b) →
 (cov : (x : S₀) → (x ≡ a) ⊎ (x ≡ b)) →
 Distinction
law0-6-reconstruction = fromDistinctCovered
```

Law 0.7: Reconstruction Is Exact

The round trip is lossless. Take a distinction, extract its four components, feed them back into the constructor: the result is definitionally equal to the original. Not propositionally equal—not "there exists a proof of equality"—but definitionally equal, meaning the type checker treats them as the same term without any proof at all. The proof is refl. This is the strongest form of exactness a reconstruction can have.

```
-- § Law 0.7: Reconstruction is exact by definitional equality.
law0-7-reconstruction-exact :
 (d : Distinction) →
 fromDistinctCovered (ℓ d) (r d) (ℓ≠r d) (cover d) ≡ d
law0-7-reconstruction-exact d = refl
```

The distinction record is stable under reconstruction: it can be decomposed into its four components and reassembled without loss. This is the sharpest form of structural identity the type system can express. The object is not merely described—it is locked.

Chapter 4

Elimination and Classification

The distinction record is established. What can be done with it?

The answer is surprisingly constrained. Two-class coverage—the guarantee that every element of the carrier equals ℓ or r—does not merely partition the carrier. It forces a radical compression of the entire function space. Any endomorphism $f : S \to S$ is completely determined by two values: $f(\ell)$ and $f(r)$. Each of these values is itself forced into one of two classes. So the total number of endomorphisms is at most $2 \times 2 = 4$. Not approximately. Exactly.

This chapter traces that compression from its source (coverage) to its consequence (the complete four-case classification that constitutes K_4).

Two-Class Coverage

Law 1.1: Carrier Coverage Is Two-Class

The coverage field is not a bonus feature of the distinction record—it is the engine that drives everything that follows. Without it, the carrier might contain elements that are neither ℓ nor r: unclassified witnesses that escape the boundary structure. With it, every element is nailed down. There is nowhere to hide.

```
– § Law 1.1: Carrier coverage is two-class.
law1-1-cover : (d : Distinction) → (x : S d) → (x ≡ ℓ d) ⊎ (x ≡ r d)
law1-1-cover = cover
```

Two-class coverage forces the first structural milestone: every surviving witness lies on one of two boundary classes. Figure 4.1 fixes this collapse as a two-node distinction diagram.

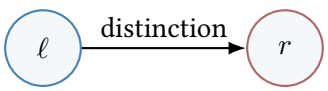

Figure 4.1: First distinction: two boundary witnesses forced by two-class coverage.

Law 1.2: Elimination Is Forced By Coverage

Coverage has a powerful consequence: it gives us a canonical eliminator. For any predicate P on the carrier, if we know $P(\ell)$ and $P(r)$, then we know $P(x)$ for every x. The proof is mechanical: ask cover which class x belongs to, then substitute the appropriate witness. This is not a convenience—it is the only way to discharge a universal statement over the carrier. The two boundary cases are all there is.

```
-- § The canonical eliminator for a distinction carrier.
Distinction-elim :
 (d : Distinction) →
 {P : S d → Set} →
 P (ℓ d) →
 P (r d) →
 (x : S d) →
 P x
Distinction-elim d {P} pℓ pr x with cover d x
... | inj₁ x≡ℓ = subst P (sym x≡ℓ) pℓ
... | inj₂ x≡r = subst P (sym x≡r) pr

-- § Law 1.2: Elimination is forced by coverage.
law1-2-elim :
 (d : Distinction) →
 {P : S d → Set} →
 P (ℓ d) →
 P (r d) →
 (x : S d) →
 P x
law1-2-elim = Distinction-elim
```

Duality

Once the carrier has exactly two classes, there is exactly one nontrivial thing you can do to it: swap the two sides. Send ℓ to r and r to ℓ. This is the dual map. It is not one permutation among many—it is the *only* non-identity permutation that a two-element carrier admits.

The critical property is involutivity: applying the swap twice returns to the starting point. This is not merely expected—it is forced. If the double application landed anywhere other than the original, it would produce a third element or violate coverage. Neither is possible. So duality is an involution, and this fact is proved by exhaustive case analysis on both boundary witnesses.

```
-- § The dual map: swap boundary cases.
Distinction-dual : (d : Distinction) → S d → S d
Distinction-dual d x with cover d x
... | inj₁ _ = r d
... | inj₂ _ = ℓ d

-- § Duality is involutive by exhaustive case analysis.
Distinction-dual-involutive :
 (d : Distinction) →
 (x : S d) →
 Distinction-dual d (Distinction-dual d x) ≡ x
Distinction-dual-involutive d =
```

```
Distinction-elim d proof-ℓ proof-r
where
 proof-ℓ : Distinction-dual d (Distinction-dual d (ℓ d)) ≡ ℓ d
 proof-ℓ with cover d (ℓ d)
 ... | inj₂ ℓ≡r = ⊥-elim ((ℓ≢r d) ℓ≡r)
 ... | inj₁ _ with cover d (r d)
 ... | inj₁ r≡ℓ = ⊥-elim ((ℓ≢r d) (sym r≡ℓ))
 ... | inj₂ _ = refl

 proof-r : Distinction-dual d (Distinction-dual d (r d)) ≡ r d
 proof-r with cover d (r d)
 ... | inj₁ r≡ℓ = ⊥-elim ((ℓ≢r d) (sym r≡ℓ))
 ... | inj₂ _ with cover d (ℓ d)
 ... | inj₂ ℓ≡r = ⊥-elim ((ℓ≢r d) ℓ≡r)
 ... | inj₁ _ = refl
```

Law 1.3: Duality Is An Involution

If the dual map were not involutive, it would generate an orbit of length three or more—but the carrier has only two elements. There is no room. The double application must return to the original, and that is exactly what the type checker confirms.

```
-- § Law 1.3: Duality is an involution.
law1-3-dual-involutive :
 (d : Distinction) →
 (x : S d) →
 Distinction-dual d (Distinction-dual d x) ≡ x
law1-3-dual-involutive = Distinction-dual-involutive
```

Pointwise Equality

When are two endomorphisms the same? The answer is forced by the elimination structure we already have. Since every carrier element is determined by its boundary class, and every endomorphism is determined by what it does to the boundary, two endomorphisms are equal precisely when they agree on every input. This pointwise equality is the only comparison that respects the boundary structure. Intensional distinctions—cases where two maps compute differently but produce identical results—are irrelevant. What matters is the output at every point, nothing else.

```
-- § Pointwise equality of functions.
infix 4 _≐_
_≐_ : {ℓ₁ ℓ₂ : Level} {A : Set ℓ₁} {B : Set ℓ₂} → (A → B) → (A → B) → Set (ℓ₁ ⊔ ℓ₂)
_≐_ {A = A} f g = (x : A) → f x ≡ g x

-- § The identity function.
id : {A : Set} → A → A
id x = x
```

Four-Case Endomorphism Classification

Now the compression becomes visible. An endomorphism $f : S \to S$ sends each boundary witness to some element of the carrier. But every element of the carrier is either ℓ or r. So $f(\ell)$ is either ℓ or r, and $f(r)$ is either ℓ or r. That gives exactly four possibilities:

- $f(\ell) = \ell$ and $f(r) = \ell$: the constant-left map.
- $f(\ell) = r$ and $f(r) = r$: the constant-right map.
- $f(\ell) = \ell$ and $f(r) = r$: the identity.
- $f(\ell) = r$ and $f(r) = \ell$: the dual.

There is no fifth case. The four labels below name these survivors.

```
– § The four-case classification of endomorphisms.
data EndoCase : Set where
 case-constL : EndoCase
 case-constR : EndoCase
 case-id     : EndoCase
 case-dual : EndoCase
```

Figure 4.2 makes the pressure visible in the negative direction. A three-vertex closure cannot survive this classification, because one of the four mutually distinct cases is always left outside. The triangle is therefore not a weaker rival to K_4; it is the first unstable alternative that the four-case verdict destroys.

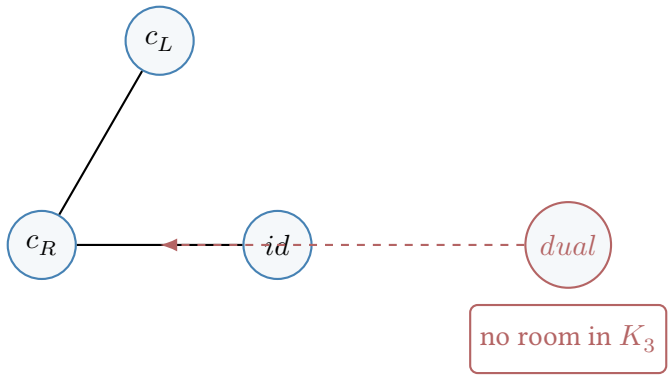

Figure 4.2: Why K_3 fails: four mutually distinct endomorphism cases cannot close on a three-vertex graph. One case is always forced outside.

The K_4 Classification Module

The four cases are not yet a classification—they are just labels. A proper classification requires three things: an *interpretation* that turns each label into an actual endomorphism, a *classifier* that assigns a label to any given endomorphism, and proofs that these two operations are inverses of

each other. Soundness (classify then interpret recovers the original) and injectivity (distinct labels produce distinct behavior) together force uniqueness: every endomorphism receives exactly one label, and no two labels describe the same map.

The module K_4 assembles all of this in one place. It is parameterized by a distinction d, because the classification depends on the specific boundary witnesses.

Step 1: Endo type and pointwise equivalence. The endomorphism type and its equivalence relation are forced by the carrier.

```
-- § K₄ endomorphism algebra: classify, interpret, and verify.
module K₄ (d : Distinction) where
  Endo : Set
  Endo = S d → S d

  ≐-refl : {f : Endo} → f ≐ f
  ≐-refl x = refl

  ≐-sym : {f g : Endo} → f ≐ g → g ≐ f
  ≐-sym p x = sym (p x)

  ≐-trans : {f g h : Endo} → f ≐ g → g ≐ h → f ≐ h
  ≐-trans p q x = trans (p x) (q x)
```

Step 2: The four canonical endomorphisms. Two-class coverage forces exactly four surviving endomorphisms: constant-left, constant-right, identity, and dual. The dual exchanges the two boundary witnesses; its boundary behavior is verified by case analysis against cover.

```
-- § Constant-left endomorphism.
constL : Endo
constL _ = ℓ d

-- § Constant-right endomorphism.
constR : Endo
constR _ = r d

-- § The dual endomorphism.
dual : Endo
dual = Distinction-dual d

-- § Dual sends ℓ to r.
dual-ℓ : dual (ℓ d) ≡ r d
dual-ℓ with cover d (ℓ d)
... | inj₁ _ = refl
... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d) ℓ≡r)

-- § Dual sends r to ℓ.
dual-r : dual (r d) ≡ ℓ d
dual-r with cover d (r d)
... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d) (sym r≡ℓ))
... | inj₂ _ = refl
```

Step 3: Interpretation and classification. Each case label is interpreted as one of the four canonical endomorphisms. Conversely, every endofunction is classified by its boundary outputs into one of the four cases.

```
-- § Interpret a case label as an endofunction.
interpret : EndoCase → Endo
interpret case-constL = constL
interpret case-constR = constR
interpret case-id     = id
interpret case-dual = dual

-- § Classify an endofunction by its boundary outputs.
classify : Endo → EndoCase
classify f with cover d (f (ℓ d)) | cover d (f (r d))
... | inj₁ _ | inj₁ _ = case-constL
... | inj₂ _ | inj₂ _ = case-constR
... | inj₁ _ | inj₂ _ = case-id
... | inj₂ _ | inj₁ _ = case-dual
```

Step 4: Soundness of classification. Classification followed by interpretation recovers the original endofunction at both boundary witnesses. The pointwise proof is assembled from the two boundary cases via the carrier eliminator.

```
-- § Soundness at ℓ: interpretation recovers the value at ℓ.
sound-at-ℓ : (f : Endo) → interpret (classify f) (ℓ d) ≡ f (ℓ d)
sound-at-ℓ f with cover d (f (ℓ d)) | cover d (f (r d))
... | inj₁ fl≡ℓ | inj₁ _ = sym fl≡ℓ
... | inj₂ fl≡r | inj₂ _ = sym fl≡r
... | inj₁ fl≡ℓ | inj₂ _ = sym fl≡ℓ
... | inj₂ fl≡r | inj₁ _ = trans dual-ℓ (sym fl≡r)

-- § Soundness at r: interpretation recovers the value at r.
sound-at-r : (f : Endo) → interpret (classify f) (r d) ≡ f (r d)
sound-at-r f with cover d (f (ℓ d)) | cover d (f (r d))
... | inj₁ _ | inj₁ fr≡ℓ = sym fr≡ℓ
... | inj₂ _ | inj₂ fr≡r = sym fr≡r
... | inj₁ _ | inj₂ fr≡r = sym fr≡r
... | inj₂ _ | inj₁ fr≡ℓ = trans dual-r (sym fr≡ℓ)

-- § Soundness: classification followed by interpretation recovers behavior.
classify-sound : (f : Endo) → interpret (classify f) ≐ f
classify-sound f x = Distinction-elim d (sound-at-ℓ f) (sound-at-r f) x
```

Step 5: Boundary determination and injectivity. Endofunctions are determined by their boundary values alone (via the eliminator). Interpretation is injective: distinct case labels force distinct boundary behavior, so the 4×4 case matrix either produces refl or derives absurdity from $\ell \neq r$.

```
-- § Endofunctions are determined by their boundary values.
endo-determined :
 (f g : Endo) →
 f (ℓ d) ≡ g (ℓ d) →
 f (r d) ≡ g (r d) →
 f ≐ g
```

```
endo-determined f g eqℓ eqr x = Distinction-elim d eqℓ eqr x

-- § Interpretation is injective: distinct cases produce distinct behavior.
interpret-injective :
 (c c' : EndoCase) →
 interpret c ≐ interpret c' →
 c ≡ c'
interpret-injective case-constL case-constL _ = refl
interpret-injective case-constL case-constR p = ⊥-elim ((ℓ≠r d) (p (ℓ d)))
interpret-injective case-constL case-id    p = ⊥-elim ((ℓ≠r d) (p (r d)))
interpret-injective case-constL case-dual  p =
 ⊥-elim ((ℓ≠r d) (trans (p (ℓ d)) dual-ℓ))

interpret-injective case-constR case-constL p =
 ⊥-elim ((ℓ≠r d) (sym (p (ℓ d))))
interpret-injective case-constR case-constR _ = refl
interpret-injective case-constR case-id    p =
 ⊥-elim ((ℓ≠r d) (sym (p (ℓ d))))
interpret-injective case-constR case-dual  p =
 ⊥-elim ((ℓ≠r d) (sym (trans (p (r d)) dual-r)))

interpret-injective case-id    case-constL p =
 ⊥-elim ((ℓ≠r d) (sym (p (r d))))
interpret-injective case-id    case-constR p = ⊥-elim ((ℓ≠r d) (p (ℓ d)))
interpret-injective case-id    case-id     _ = refl
interpret-injective case-id    case-dual   p =
 ⊥-elim ((ℓ≠r d) (trans (p (ℓ d)) dual-ℓ))

interpret-injective case-dual case-constL p =
 ⊥-elim ((ℓ≠r d) (sym (trans (sym (dual-ℓ)) (p (ℓ d)))))
interpret-injective case-dual case-constR p =
 ⊥-elim ((ℓ≠r d) (trans (sym (dual-r)) (p (r d))))
interpret-injective case-dual case-id      p =
 ⊥-elim ((ℓ≠r d) (sym (trans (sym (dual-ℓ)) (p (ℓ d)))))
interpret-injective case-dual case-dual    _ = refl
```

Step 6: Classification uniqueness. Soundness and injectivity together force that the case label assigned by classify is unique.

```
-- § Classification is unique: the label is forced by soundness + injectivity.
classify-unique : (f : Endo) → (c : EndoCase) → interpret c ≐ f → c ≡ classify f
classify-unique f c c≐f =
 interpret-injective c (classify f) (≐-trans c≐f (≐-sym (classify-sound f)))
```

Mutual Distinctness of Cases

The four case labels must remain genuinely different—no two of them may be identified. This is not something that requires deep reasoning. The labels are constructors of a data type, and Agda's pattern matching confirms that no constructor equals any other. The six pairwise inequalities are all proved by the absurd pattern (): there is simply no way to build a proof that, say, case-constL equals case-id. The type is empty.

```
-- § All four EndoCase constructors are pairwise distinct.
EndoCase-distinct :
```

```
 (case-constL ≡ case-constR → ⊥) ×
 (case-constL ≡ case-id     → ⊥) ×
 (case-constL ≡ case-dual → ⊥) ×
 (case-constR ≡ case-id     → ⊥) ×
 (case-constR ≡ case-dual → ⊥) ×
 (case-id ≡ case-dual       → ⊥)
EndoCase-distinct =
 (λ ()) ,
 ((λ ()) ,
  ((λ ()) ,
   ((λ ()) ,
    ((λ ()) ,
     (λ ))))))
```

Top-Level Classification Witnesses

The local module laws force exported witnesses of soundness and uniqueness. These witnesses are thin wrappers—they add no new content, only accessibility. The classification lives inside the parameterized module K_4; to use it in later chapters, we export soundness and uniqueness at the top level.

```
– § Top-level K₄ soundness witness.
k4-classification-sound :
 (d : Distinction) →
 (f : S d → S d) →
 Σ EndoCase (λ c → K₄.interpret d c ≐ f)
k4-classification-sound d f = K₄.classify d f , K₄.classify-sound d f

– § Top-level K₄ uniqueness witness.
k4-classification-unique :
 (d : Distinction) →
 (f : S d → S d) →
 (c₁ c₂ : EndoCase) →
 K₄.interpret d c₁ ≐ f →
 K₄.interpret d c₂ ≐ f →
 c₁ ≡ c₂
k4-classification-unique d f c₁ c₂ p₁ p₂ =
 K₄.interpret-injective d c₁ c₂ (K₄.≐-trans d p₁ (K₄.≐-sym d p₂))
```

Law 1.4: Endo(S) Classifies Into Exactly Four Cases

Every endomorphism on a distinction carrier receives a label from the four-case type. The classifier inspects the two boundary outputs and assigns the unique matching case. No endomorphism escapes classification.

```
– § Law 1.4: Endo(S) classifies into exactly four cases.
law1-4-classify : (d : Distinction) → (S d → S d) → EndoCase
law1-4-classify d = K₄.classify d
```

Law 1.5: Classification Is Sound

Soundness means that the round trip works: classify an endomorphism, interpret the resulting label, and you get back a function that agrees with the original at every point. This is not a design

goal—it is forced by the fact that classification reads off the boundary values and interpretation plugs them back in.

```
-- § Law 1.5: Classification is sound.
law1-5-classify-sound : (d : Distinction) → (f : S d → S d) → K₄.interpret d (K₄.classify d f) ≐ f
law1-5-classify-sound d f = snd (k4-classification-sound d f)
```

Law 1.6: Endo Is Determined By Boundary Values

If two endomorphisms agree on ℓ and agree on r, they agree everywhere. This is a direct consequence of coverage: every carrier element is either ℓ or r, so agreement on those two points leaves no room for disagreement anywhere else. The interior of the carrier is empty—there are no hidden witnesses where the two maps could diverge.

```
-- § Law 1.6: Endo is determined by boundary values.
law1-6-endo-determined :
 (d : Distinction) →
 (f g : S d → S d) →
 f (ℓ d) ≡ g (ℓ d) →
 f (r d) ≡ g (r d) →
 f ≐ g
law1-6-endo-determined d = K₄.endo-determined d
```

Law 1.7: Classification Is Unique

If a case label c interprets to a function that agrees pointwise with f, then c must be exactly the label that the classifier assigns to f. The proof chains soundness (the classifier's label also interprets correctly) with injectivity (two labels interpreting to the same function must be equal). There is no ambiguity, no alternative labeling. The classification is canonical.

```
-- § Law 1.7: Classification is unique.
law1-7-classify-unique :
 (d : Distinction) →
 (f : S d → S d) →
 (c : EndoCase) →
 K₄.interpret d c ≐ f →
 c ≡ K₄.classify d f
law1-7-classify-unique d f c p =
 k4-classification-unique d f c (fst (k4-classification-sound d f)) p (snd (k4-classification-sound d f))
```

Exhaustive classification reaches the second structural milestone here. Figure 4.3 fixes the unique four-case closure as the complete graph K_4.

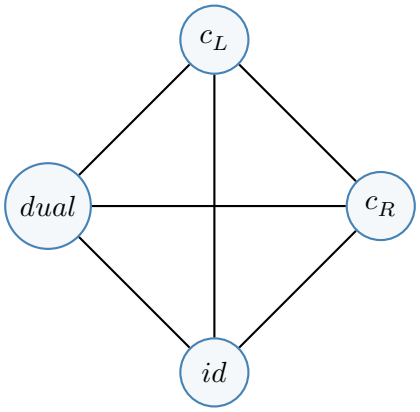

Figure 4.3: Exhaustive four-case endomorphism classification closes as the complete graph K_4.

Chapter 5

Two Normal Form

The classification is complete: every endomorphism falls into one of four cases. But the carrier itself—the type S in the distinction record—is still abstract. We know it has exactly two elements, because coverage says so. But "having exactly two elements" and "being the canonical two-element type" are different statements. This chapter closes the gap.

The key insight is that coverage forces a canonical isomorphism between any distinction carrier and a concrete two-element type Two. The maps in both directions are uniquely determined by the boundary witnesses, the round trips are identity, and the only remaining freedom is a binary choice: do we send ℓ to L or to R? That choice is the orientation, and there are exactly two of them. The same compression applies to automorphisms: the only self-equivalences of a distinction are the identity and the dual.

The Two Type

The canonical two-element type has two constructors—L and R—that are provably distinct and exhaustively cover the type. This is the simplest possible distinction. It serves as the solved form: the concrete representative to which every abstract distinction carrier is isomorphic.

```
-- § The canonical two-element type.
data Two : Set where
  L : Two
  R : Two

-- § L and R are distinct.
Two-L≠R : L ≠ R
Two-L≠R ()

-- § Exhaustive two-class coverage for Two.
Two-cover : (x : Two) → (x ≡ L) ⊎ (x ≡ R)
Two-cover L = inj₁ refl
Two-cover R = inj₂ refl

-- § Two forms a canonical Distinction.
Two-distinction : Distinction
Two-distinction = record
  { S     = Two
  ; ℓ     = L
```

```
; r     = R
; ℓ≠r = Two-L≠R
; cover = Two-cover
}
```

This definition settles the existence question that Chapter 3 deliberately left open. Two-distinction is a parameterless, fully constructive inhabitant of Distinction—no assumptions, no function arguments, no postulates. The ¬¬ *Distinction* barrier that blocked vacuity is upgraded to direct constructive existence: $\lambda\, f \to f$ *Two-distinction* discharges the double negation trivially. Every subsequent chapter inherits this witness.

Distinction Isomorphism

Comparing two distinctions requires a notion of structural equivalence. A *distinction isomorphism* is a pair of maps between the carriers that are mutual inverses and that preserve the boundary witnesses: ℓ maps to ℓ and r maps to r. A weaker notion—*distinction equivalence*—drops the boundary requirement and retains only the inverse laws. The weaker notion is what orientation and automorphism classification will use, since those questions ask precisely whether the boundary is preserved or swapped.

```
-- § Boundary-preserving isomorphism between distinctions.
record DistinctionIso (d₁ d₂ : Distinction) : Set1 where

 }
```

Canonical Two Maps

The isomorphism between any distinction carrier and Two writes itself. The forward map toTwo sends ℓ to L and r to R—determined by coverage. The backward map fromTwo reverses this. The round-trip proofs are forced by the eliminator: there is exactly one way to verify that the composition is the identity, and the type checker accepts it.

```
-- § The canonical boundary-preserving map to Two.

-- § toTwo ∘ fromTwo is the identity.
toTwo-fromTwo : (d : Distinction) → (t : Two) → toTwo d (fromTwo d t) ≡ t
toTwo-fromTwo d L = toTwo-ℓ d
toTwo-fromTwo d R = toTwo-r d
```

Law 1.8: Every Distinction Is Isomorphic To Two

This is the normal form theorem. Every distinction—regardless of how its carrier was originally defined—is boundary-preserving isomorphic to the canonical Two distinction. The proof assembles the maps and round-trip verifications from the previous section into a single record. There is nothing to choose; every field is forced.

```
-- § Law 1.8: Every distinction is isomorphic to Two.
two-normal-form : (d : Distinction) → DistinctionIso d Two-distinction
two-normal-form d = record
 { to      = toTwo d
 ; from    = fromTwo d
 ; to-from = toTwo-fromTwo d
 ; from-to = fromTwo-toTwo d
```

```
 ; to-ℓ  = toTwo-ℓ d
 ; to-r  = toTwo-r d
 }

law1-8-two-normal-form : (d : Distinction) → DistinctionIso d Two-distinction
law1-8-two-normal-form = two-normal-form
```

Orientation

An equivalence between a distinction and Two must send the two boundary witnesses to distinct images—otherwise the inverse map would identify ℓ and r, contradicting their separation. The images are elements of Two, which has only two inhabitants. So there are exactly two possibilities: send ℓ to L (preserve) or send ℓ to R (swap). No third option exists.

```
-- § The swap map on Two.
swapTwo : Two → Two
swapTwo L = R
swapTwo R = L

-- § Swap is involutive.
swapTwo-involutive : (t : Two) → swapTwo (swapTwo t) ≡ t
swapTwo-involutive L = refl
swapTwo-involutive R = refl

-- § The swap-oriented map to Two.
toTwo-swap : (d : Distinction) → S d → Two
toTwo-swap d x = swapTwo (toTwo d x)

-- § Swap-oriented map sends ℓ to R.

 (d : Distinction) →
 (e : DistinctionEquiv d Two-distinction) →
 TwoOrientation
orientation-classify d e with Two-cover (to e (ℓ d)) | Two-cover (to e (r d))
... | inj₁ tℓ≡L | inj₁ tr≡L = ⊥-elim (to-distinct-on-boundary d e (trans tℓ≡L (sym tr≡L)))
... | inj₂ tℓ≡R | inj₂ tr≡R = ⊥-elim (to-distinct-on-boundary d e (trans tℓ≡R (sym tr≡R)))
... | inj₁ _ | inj₂ _ = orient-preserve
... | inj₂ _ | inj₁ _ = orient-swap
```

Automorphisms

An automorphism of a distinction is a self-equivalence: a pair of maps from the carrier to itself that are mutual inverses. The inverse law forces injectivity, and injectivity forces the boundary images to remain distinct (since $\ell \neq r$ would be violated otherwise). With only two elements in the carrier, the only injective endomorphisms are the identity and the swap. That is the complete automorphism group of any distinction: exactly two elements, id and dual.

```
-- § Automorphism of a distinction.
Aut : Distinction → Set1
Aut d = DistinctionEquiv d d

-- § Automorphism transport is injective.
to-injective : (d : Distinction) → (a : Aut d) → {x y : S d} → to a x ≡ to a y → x ≡ y
to-injective d a {x} {y} eq =
 trans (sym (from-to a x)) (trans (cong (from a) eq) (from-to a y))

-- § Automorphism images at boundary points are distinct.
to-ℓ≠to-r : (d : Distinction) → (a : Aut d) → to a (ℓ d) ≠ to a (r d)
to-ℓ≠to-r d a eq = ℓ≠r d (to-injective d a eq)

-- § Dual boundary lemma: dual sends ℓ to r.
Distinction-dual-ℓ : (d : Distinction) → Distinction-dual d (ℓ d) ≡ r d
Distinction-dual-ℓ d with cover d (ℓ d)
... | inj₁ _    = refl
```

```
... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d) ℓ≡r)

-- § Dual boundary lemma: dual sends r to ℓ.
Distinction-dual-r : (d : Distinction) → Distinction-dual d (r d) ≡ ℓ d

... | inj₂ _     = refl
... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d) (sym r≡ℓ))

-- § Automorphism classification: exactly id or dual.
Aut-sound :
 (d : Distinction) →
 (a : Aut d) →
 (to a ≐ id) ⊎ (to a ≐ Distinction-dual d)
Aut-sound d a with cover d (to a (ℓ d)) | cover d (to a (r d))
... | inj₁ tℓ≡ℓ | inj₁ tr≡ℓ = ⊥-elim (to-ℓ≠to-r d a (trans tℓ≡ℓ (sym tr≡ℓ)))
... | inj₂ tℓ≡r | inj₂ tr≡r = ⊥-elim (to-ℓ≠to-r d a (trans tℓ≡r (sym tr≡r)))
... | inj₁ tℓ≡ℓ | inj₂ tr≡r =
 inj₁ (Distinction-elim d tℓ≡ℓ tr≡r)
... | inj₂ tℓ≡r | inj₁ tr≡ℓ =
 inj₂ (Distinction-elim d
  (trans tℓ≡r (sym (Distinction-dual-ℓ d)))
  (trans tr≡ℓ (sym (Distinction-dual-r d))))
```

Automorphism classification reaches the third structural milestone here. Figure 5.1 fixes the symmetry action as a permutation of the four case witnesses.

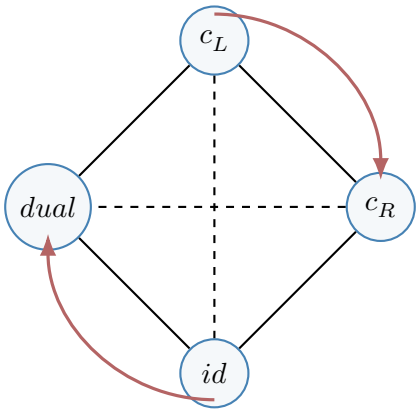

Figure 5.1: Automorphism action on the four-case witness space: preserve and swap survive as the only orbit structure.

Law 1.9: The Two Isomorphism Is Unique

Any boundary-preserving map from a distinction carrier to Two must agree with the canonical map toTwo. The proof is immediate from the eliminator: since the map is determined by its values at ℓ and r, and those values are fixed by the boundary-preservation requirement, there is exactly one such map. The same holds for the backward direction.

```
-- § Uniqueness of the to-direction.
toTwo-unique :
 (d : Distinction) →
 (f : S d → Two) →
 f (ℓ d) ≡ L →
```

```
 f (r d) ≡ R →

 fromTwo-unique d (from i)
  (trans (sym (cong (from i) (to-ℓ i))) (from-to i (ℓ d)))
  (trans (sym (cong (from i) (to-r i))) (from-to i (r d)))
```

Law 1.10: Two Normal Form Has Exactly Two Orientations

Every equivalence to Two is either the canonical boundary-preserving map or the swap. The proof checks the image of ℓ: it is either L or R. If L, the map agrees with toTwo. If R, it agrees with toTwo-swap. There is no third possibility, because Two has no third element.

```
– § Law 1.10: orientation is exhaustive.
orientation-exhaustive :
 (d : Distinction) →
 (e : DistinctionEquiv d Two-distinction) →
 (to e ≐ toTwo d) ⊎ (to e ≐ toTwo-swap d)

law1-10-orientation-exhaustive = orientation-exhaustive
```

Law 1.11: Automorphisms Are Exactly id Or dual

The boundary behavior of any automorphism is forced into one of two patterns: fix both boundaries (identity) or swap both (dual). Any other combination—fixing one and moving the other—would produce a non-injective map, which contradicts the inverse law.

```
-- § Law 1.11: Automorphisms are exactly id or dual.
law1-11-Aut-sound :
 (d : Distinction) →
 (a : Aut d) →
 (to a ≐ id) ⊎ (to a ≐ Distinction-dual d)
law1-11-Aut-sound = Aut-sound
```

Law 1.12: Two-Orientation Classification Is Sound And Unique

The orientation classifier assigns every equivalence to Two one of two labels: case-preserve or case-swap. Soundness: the assigned label interprets back to a map that agrees pointwise with the original equivalence. Uniqueness: no equivalence can receive two different labels, because that would force $L = R$ in Two.

```
-- § Orientation case type.

```

Law 1.13: Automorphism Classification Is Sound And Unique

The same structure holds for automorphisms. Every self-equivalence receives exactly one label—case-id or case-dual—and that label is forced by the boundary behavior. If two different labels could describe the same automorphism, their interpretations would agree pointwise, which would force $\ell = r$ via the boundary lemmas. Contradiction eliminates every unsound or non-unique automorphism witness.

```

Two-Class Coverage Without Definitional Equality

Everything so far has relied on propositional equality ≡ as the notion of sameness. But some contexts require coverage with respect to a weaker equivalence relation ≈ that is reflexive, symmetric, and transitive but not necessarily definitional. The record DistinctionClass captures this: it carries a carrier, two separated boundary witnesses, an equivalence relation, and exhaustive coverage under that relation. This weakening does not gain expressive power—it broadens the range of carriers that can be recognized as distinctions without altering the classification theory.

```

Presentation Elimination

The four-case classification is canonical, but nothing prevents someone from proposing an alternative presentation: a different type X with its own interpretation and classification functions. The question is whether such an alternative can differ structurally from EndoCase. The answer is no. If a presentation is total (every endomorphism gets a label), sound (the label interprets back correctly), and injective (distinct labels produce distinct behavior), then X is isomorphic to EndoCase. The proof constructs the isomorphism explicitly by round-tripping through the canonical classifier.

```

The primitive distinction is stable. Equality, negation, decidability, witness structure, and the four endomorphism cases exist as machine-checked constraints on a two-element carrier. The base classification is locked.

But a classification that is not itself classified leaves a residue outside the filter. The next pressure is therefore unavoidable: the classifier must become an object inside the argument, and the argument must climb.

A number to remember. Four endomorphism cases have survived elimination. This number was not chosen—it fell out of the exhaustive analysis of a two-element carrier. It will reappear. When the argument finally converges on a graph, that graph will have exactly four vertices, and the combinatorial invariants of that graph—edge count, Euler characteristic, spectral decomposition—will produce specific integers. The reader who notices the number four here and remembers it through the next hundred pages will recognize it again in a less abstract setting.

Part II

Drift and Reachability

Every act of classification produces a new unclassified object: the classification record itself. This is not a failure of the method—it is a structural property of any system that takes classification seriously. The minimal response is not to stop but to classify again, one level higher, each time inheriting the exact structure of the level below.

The result is a canonical tower. Agda's universe hierarchy is not an external convention imposed on the argument; it is the shape the argument is forced to take. The reachability proofs in this part are the formal record of ascent through that tower: which levels are accessible from which, and by what minimal paths.

Chapter 6

Drift

The classification is complete at a single level: every endomorphism on a distinction carrier falls into one of four cases. But the classification itself—the type EndoCase, the classifier function, the interpretation—is a new piece of mathematical structure. And this new structure is not yet classified. If we stop here, we leave an unclassified object in our ontology, which is exactly the kind of residual freedom our filter is designed to eliminate.

The resolution is forced: classify the classifier. But to do so, the carrier must grow—the new classification lives at a higher universe level, because it quantifies over the objects of the previous level. This is drift: the canonical step from one level to the next, carrying the old distinction into a lifted carrier that can accommodate the expanded ontology.

The drift step is not a construction we invent. It is the minimal response to a structural demand: every classification must itself be classifiable, and the type-theoretic hierarchy of universe levels is the unique mechanism that makes this possible without circularity.

 cover↑ (lift x) with cover d x
 ... | inj₁ x≡ℓ = inj₁ (cong lift x≡ℓ)
 ... | inj₂ x≡r = inj₂ (cong lift x≡r)
```

Law 2.1: No Classification May Remain Unclassified

This is the law of closure. If a classification exists in the system, it must be classifiable—otherwise it sits outside the filter, untouched by elimination, a free parameter. The drift step provides the necessary embedding: the old carrier lifts into the new one, and the boundary witnesses lift with it.

```
-- § Law 2.1: No classification may remain unclassified.
law2-1-drift : {ℓ : Level} → (d : Distinctionℓ ℓ) → DriftStep d
law2-1-drift = drift

-- § Extract the next-level distinction from a drift step.

-- § Drift-embedded elements satisfy coverage.
drift-embed-cover : {ℓ : Level} → (d : Distinctionℓ ℓ) → (x : S d)
 → (drift-embed d x ≡ ℓ₀ (drift-next d)) ⊎ (drift-embed d x ≡ r₀ (drift-next d))
drift-embed-cover d x = cover (drift-next d) (drift-embed d x)
```

Drift is established: it lifts any distinction one universe level higher, preserving the boundary and coverage structure verbatim. The question that remains is whether this lift is safe—whether it distorts the carrier it inherits.

Chapter 7

Non-Collapse of Drift

Drift lifts the carrier to a higher universe level via lift. The critical question: does this lifting identify elements that were previously distinct? If it did, the boundary structure of the old distinction would collapse—ℓ and r might become equal in the lifted carrier. But lift is injective (its inverse lower is a witness), so the old separation survives verbatim. Drift expands the universe without folding the carrier.

Law 3.1: Drift Does Not Fold The Prior Carrier

The proof is immediate: lift has an inverse (lower), so any equation between lifted images reflects back to the originals. Boundary distinctness survives as a corollary—if ℓ_0 and r_0 could become equal after embedding, they would already be equal before it.

```
-- § Law 3.1: Drift does not fold the prior carrier.
law3-1-embed-injective :
 {ℓ : Level} (d : Distinctionℓ ℓ) → {x y : S d} →
 drift-embed d x ≡ drift-embed d y → x ≡ y
law3-1-embed-injective d = lift-injective

-- § Drift preserves boundary distinctness.
drift-embed-ℓ₀≠r₀ :
 {ℓ : Level} (d : Distinctionℓ ℓ) →
 drift-embed d (ℓ₀ d) ≠ drift-embed d (r₀ d)
drift-embed-ℓ₀≠r₀ d eq = ℓ₀≠r₀ d (law3-1-embed-injective d eq)
```

The lift is injective and the boundary separation survives. Drift expands the universe without folding the carrier. The next question is whether drift is unique among lifts that preserve this structure.

Chapter 8

Cross-Stage Comparison

Drift produces the simplest possible lift: lift wraps each element, and the boundary witnesses are preserved by refl. But there might be other ways to embed a distinction into a higher level—other choices of target carrier and embedding map that also preserve the boundary structure. The question is whether drift is in any way special among these alternatives.

It is. Drift is *universal*: for any boundary-preserving lift, there exists a unique mediating map from the drift carrier to the alternative carrier that makes the diagram commute. This is the universal property in the categorical sense—drift is the initial object in the category of boundary-preserving lifts. Any alternative lift factors through drift, and the factorization is unique.

drift-factor-unique d t m =
 mediator-unique d t (map m) (comm m)
```

Law 4.2: Drift-Step Factorization Is Unique

If two mediating maps both make the diagram commute, they must agree at the boundary—and by the determination principle, agreement at the boundary forces agreement everywhere. There is no room for a second factorization.

```
-- § Law 4.2: Drift-step factorization is unique.
law4-2-factor-unique :
 {ℓ : Level} (d : Distinctionℓ ℓ) → (t : LiftedBP d) →
 (m : LiftMorph d (driftLiftedBP d) t) →
 map m ≐ mediator driftUniversal d t
law4-2-factor-unique = drift-factor-unique
```

Drift is universal: every boundary-preserving lift factors through it, and the factorization is unique. No alternative lift can bypass the drift step. The tower is therefore canonical—what remains is to trace how far the chain reaches.

Chapter 9

Drift Reachability

Drift does not stop. There is no final universe level where the process terminates—every distinction at level ℓ drifts to level $\ell + 1$, and that lifted distinction drifts again. The reachability relation captures this infinite progression: state t is reachable from state s if there is a finite chain of drift steps connecting them. Strict reachability (Reach^+) requires at least one step; reflexive-transitive reachability (Reach) allows zero.

The key structural facts follow from the uniqueness of successors. Since each drift state has exactly one successor, there is no branching—the reachability order is a total preorder on any connected chain. Every finite chain extends by one more step. And the chain never loops back (as the next chapter proves).

reach-embed {s} (next p) x = reach⁺-embed p x
```

Law 5.0: Drift Admits No Terminal State

If a terminal state existed, then the strict successor forced by Reach⁺.one would contradict terminality.

```
– § Law 5.0: Drift admits no terminal state.
law5-0-no-terminal : (s : DriftState) → Terminal s → ⊥
law5-0-no-terminal = no-terminal
```

Law 5.1: Strict Successors Are Comparable

Any two states strictly reachable from the same source must be comparable: one reaches the other. This is forced by the linear structure of drift—each step adds exactly one new state, so the reachability chain cannot branch.

```
– § Law 5.1: Strict successors are comparable.
law5-1-comparable :
 {s t₁ t₂ : DriftState} →
 s ≺ t₁ →
 s ≺ t₂ →
 (Reach t₁ t₂) ⊎ω (Reach t₂ t₁)
law5-1-comparable = Reach⁺-comparable
```

Law 5.2: Every Finite Chain Extends

Every finite chain of drift steps can be extended by one more step. This witnesses the non-termination of drift: no matter how far the chain reaches, stepState always produces a fresh successor.

```
– § Law 5.2: Every finite chain extends (strict).
law5-2-extend⁺ :
 {s t : DriftState} →
 s ≺ t →
 s ≺ stepState t
law5-2-extend⁺ p = Reach⁺-extend p
```

```
– § Law 5.2: Every finite chain extends (reflexive).
law5-2-extend :
 {s t : DriftState} →
 Reach s t →
 Reach s (stepState t)
law5-2-extend = Reach-extend
```

Laws 5.3–5.7: Closure and Induction

The remaining structural laws—transitivity of strict and reflexive reachability, the carrier-embedding forced by each reachability witness, and the eliminators for both Reach^+ and Reach—are direct consequences of the inductive definitions. They close the reachability algebra and provide the induction principles that all later arguments over drift chains will invoke.

```
– § Law 5.3: Strict reachability is transitive.
law5-3-≺-trans : {s t u : DriftState} → (s ≺ t) → (t ≺ u) → (s ≺ u)
law5-3-≺-trans = ≺-trans

– § Law 5.4: Reachability is transitive.
law5-4-reach-trans : {s t u : DriftState} → Reach s t → Reach t u → Reach s u
law5-4-reach-trans = reach-trans

– § Law 5.5: Reachability forces carrier-embedding.
law5-5-reach-embed : {s t : DriftState} → Reach s t → Carrier s → Carrier t
law5-5-reach-embed = reach-embed

– § Law 5.6: Reach⁺ eliminator is forced.
law5-6-Reach⁺-elim :
 {P : (s t : DriftState) → Reach⁺ s t → Setω} →
 ({s : DriftState} → P s (stepState s) one) →
 ({s t : DriftState} → (p : Reach⁺ (stepState s) t) → P (stepState s) t p → P s t (more p)) →
 {s t : DriftState} → (p : Reach⁺ s t) → P s t p
law5-6-Reach⁺-elim = Reach⁺-elim

– § Law 5.7: Reach eliminator is forced.
law5-7-Reach-elim :
 {P : (s t : DriftState) → Reach s t → Setω} →
 ({s : DriftState} → P s s stop) →
 ({s t : DriftState} → (p : Reach⁺ s t) → P s t (next p)) →
 {s t : DriftState} → (p : Reach s t) → P s t p
law5-7-Reach-elim = Reach-elim
```

Reachability is explicit: every finite chain extends, strict successors are comparable, and the eliminator is forced. The chain stretches forward without bound. The last structural hazard is circularity—whether the chain could loop back and collapse the hierarchy it has built.

Chapter 10

Drift Acyclicity

A tower that never stops climbing is not safe merely because it grows. If a chain of drift steps could fold back on itself—returning to a state already visited—then the hierarchy would collapse into a finite loop, and the infinite ascent would be an illusion. Everything established so far would apply only to a cycle, not to a genuine progression. The elimination strategy demands that the tower be rigid: once a state is left behind, it is left behind permanently.

The drift sequence is infinite—but is it linear? Could a chain of drift steps loop back to a previous state? If it could, then a distinction at some level ℓ would be identified with a distinction at a higher level $\ell + k$, collapsing the universe hierarchy. This is structurally impossible: universe levels in Agda are well-ordered, and lsuc is strictly increasing. But the formal system must witness this impossibility explicitly. The acyclicity constraint states that no drift state is strictly reachable from itself, and the consequences—irreflexivity, asymmetry, and absence of fixed points—follow immediately.

```
-- § Acyclicity constraint on drift.
record DriftAcyclic : Setω where
 field
  no-cycle : (s : DriftState) → (s ≺ s) → ⊥

open DriftAcyclic public
```

Law 6.0: Drift Has No Cycles

Acyclicity is recorded as a constraint: any cycle $s \prec s$ leads to absurdity. The implementation extracts the contradiction directly from the DriftAcyclic record.

```
-- § Law 6.0: Drift has no cycles.
law6-0-no-cycle : DriftAcyclic → (s : DriftState) → (s ≺ s) → ⊥
law6-0-no-cycle ac s p = no-cycle ac s p
```

Law 6.1: Strict Reachability Is Irreflexive

Irreflexivity is the immediate instance of acyclicity: $s \prec s$ is itself a cycle of length one.

```
-- § Law 6.1: Strict reachability is irreflexive.
law6-1-irreflexive : DriftAcyclic → (s : DriftState) → (s ≺ s) → ⊥
law6-1-irreflexive ac s = no-cycle ac s
```

Law 6.2: Strict Reachability Is Asymmetric

If both $s \prec t$ and $t \prec s$ held, transitivity would produce the cycle $s \prec s$, contradicting acyclicity.

```
-- § Law 6.2: Strict reachability is asymmetric.
law6-2-asymmetric :
 DriftAcyclic → {s t : DriftState} →
 (s ≺ t) → (t ≺ s) → ⊥
law6-2-asymmetric ac p q = no-cycle ac _ (≺-trans p q)
```

Law 6.3: Drift-Step Has No Fixed Point

If stepState s equalled s, then the single-step witness one could be transported into a self-loop $s \prec s$, contradicting acyclicity.

```
-- § Law 6.3: Drift-step has no fixed point.
law6-3-no-fixpoint-stepState : DriftAcyclic → (s : DriftState) → stepState s ≡ω s → ⊥
law6-3-no-fixpoint-stepState ac s eq =
 no-cycle ac s (substω (λ u → Reach⁺ s u) eq one)
```

Law 6.4: Drift Is a Strict Total Order

The pieces are now in place. Strict reachability $\prec$ is transitive (Law 5.3), comparable (Law 5.1), and—under acyclicity—irreflexive (Law 6.1) and asymmetric (Law 6.2). These four properties together constitute a strict total order on the set of drift states. The following record bundles them as a single citable theorem. No new proof work is required: every field is a direct appeal to an already-established law.

In ordinal-theoretic terms, the drift hierarchy is order-isomorphic to an initial segment of ω. Each state occupies a unique position in the progression; no branching occurs (comparability), no regression occurs (asymmetry), and no stagnation occurs (irreflexivity). The tower is rigid.

Constraint: A hierarchy without a total order could branch or merge, allowing two incomparable development paths. Rigidity demands that any two states stand in a definite before-or-after relation.

Elimination: Branching fails because comparability is forced by the linear structure of drift. Regression fails because asymmetry follows from acyclicity. Stagnation fails because irreflexivity follows from the same acyclicity. Every alternative to a strict total order is thereby annihilated.

Consequence: The drift hierarchy admits no alternative ordering. The progression is determined, the sequence is unique, and the ordinal type of the tower is ω.

```
-- § Strict total order on drift states
record DriftStrictTotalOrder (ac : DriftAcyclic) : Setω where
 field
```

```
  sto-trans       : {s t u : DriftState} → (s ≺ t) → (t ≺ u) → (s ≺ u)
  sto-irrefl      : (s : DriftState) → (s ≺ s) → ⊥
  sto-asym        : {s t : DriftState} → (s ≺ t) → (t ≺ s) → ⊥
  sto-comparable : {s t₁ t₂ : DriftState} →
                    s ≺ t₁ → s ≺ t₂ → (Reach t₁ t₂) ⊎ω (Reach t₂ t₁)

– § Theorem: drift is a strict total order
theorem-drift-strict-total-order :
 (ac : DriftAcyclic) → DriftStrictTotalOrder ac
theorem-drift-strict-total-order ac = record
 { sto-trans = law5-3-≺-trans
 ; sto-irrefl  = law6-1-irreflexive ac
 ; sto-asym = law6-2-asymmetric ac
 ; sto-comparable = law5-1-comparable
 }
```

The climb through the universe hierarchy is explicit. Drift does not terminate, reachability records the ascent, and acyclicity prevents the hierarchy from folding back onto itself. The argument carries vertical structure without losing rigidity.

But that is still not enough. If the four surviving cases depended on the source and target being the same carrier, then the classification would be parochial rather than structural. The next task is therefore to remove that loophole.

Part III

Heteromorphisms and Presentation

The classification established in Part I was confined to maps from a distinction carrier to itself. The question now is whether relaxing that restriction changes anything. It does not. Maps between two distinct carriers face the same combinatorial constraints that produced four endomorphisms, and exactly four cases survive here as well.

This consistency matters. It confirms that the classification is not an artefact of the self-mapping assumption but a structural property of a two-element distinction, regardless of which carrier provides the domain and which the codomain. The presentation theorems that follow press this further: every reachability fact between levels reduces to a finite canonical record, and every canonical record to its minimal representative.

Chapter 11

Heteromorphisms

So far, classification has been confined to endomorphisms—maps from a single distinction carrier to itself. But nothing in the argument is specific to the source and target being the same. A map $f : S_{d_1} \to S_{d_2}$ between two distinct distinction carriers is just as rigidly constrained: its behavior is determined by its values at the two boundary points of the source, and each of those values is forced into one of the two boundary classes of the target. The same 2×2 combinatorics applies. The same four cases survive.

This chapter lifts the entire classification machinery—interpretation, classification, soundness, injectivity, uniqueness—from the endomorphism setting to the heteromorphism setting. The proofs are structurally identical; only the types change. The four canonical maps between two distinctions are: constant-left, constant-right, the boundary-preserving map (LR), and the boundary-swapping map (RL).

Step 1: Map type and canonical inter-distinction maps. The map type, pointwise equivalence, and four canonical maps between two distinction-carriers mirror the endomorphism case. The two mixed maps LR and RL use source-side coverage to assign the appropriate target boundary witness.

```
-- § K₄ maps between two distinctions.
module K₄Map (d₁ d₂ : Distinction) where
  Map : Set
  Map = S d₁ → S d₂

-- § Pointwise equality on maps.
≐-refl : {f : Map} → f ≐ f
≐-refl x = refl

≐-sym : {f g : Map} → f ≐ g → g ≐ f
≐-sym p x = sym (p x)

≐-trans : {f g h : Map} → f ≐ g → g ≐ h → f ≐ h
≐-trans p q x = trans (p x) (q x)

-- § The four canonical maps.
constL : Map
constL _ = ℓ d₂
```

```
constR : Map
constR _ = r d₂

LR : Map
LR x with cover d₁ x
... | inj₁ _ = ℓ d₂
... | inj₂ _ = r d₂

RL : Map
RL x with cover d₁ x
... | inj₁ _ = r d₂
... | inj₂ _ = ℓ d₂

-- § Boundary behavior of LR.
LR-ℓ : LR (ℓ d₁) ≡ ℓ d₂
LR-ℓ with cover d₁ (ℓ d₁)
... | inj₁ _ = refl
... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d₁) ℓ≡r)

LR-r : LR (r d₁) ≡ r d₂
LR-r with cover d₁ (r d₁)
... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d₁) (sym r≡ℓ))
... | inj₂ _ = refl

-- § Boundary behavior of RL.
RL-ℓ : RL (ℓ d₁) ≡ r d₂
RL-ℓ with cover d₁ (ℓ d₁)
... | inj₁ _ = refl
... | inj₂ ℓ≡r = ⊥-elim ((ℓ≠r d₁) ℓ≡r)

RL-r : RL (r d₁) ≡ ℓ d₂
RL-r with cover d₁ (r d₁)
... | inj₁ r≡ℓ = ⊥-elim ((ℓ≠r d₁) (sym r≡ℓ))
... | inj₂ _ = refl
```

Step 2: Interpretation and classification of inter-distinction maps. Each EndoCase label interprets as one of the four canonical maps, and every concrete map is classified by its boundary outputs.

```
-- § Interpret an EndoCase as a map between distinctions.
interpret : EndoCase → Map
interpret case-constL = constL
interpret case-constR = constR
interpret case-id     = LR
interpret case-dual = RL

-- § Classify a map by its boundary behavior.
classify : Map → EndoCase
classify f with cover d₂ (f (ℓ d₁)) | cover d₂ (f (r d₁))
... | inj₁ _ | inj₁ _ = case-constL
... | inj₂ _ | inj₂ _ = case-constR
... | inj₁ _ | inj₂ _ = case-id
... | inj₂ _ | inj₁ _ = case-dual
```

Step 3: Soundness of inter-distinction classification. Classification followed by interpretation recovers the original map at both boundary witnesses.

```
– § Soundness at ℓ.
sound-at-ℓ : (f : Map) → interpret (classify f) (ℓ d₁) ≡ f (ℓ d₁)
sound-at-ℓ f with cover d₂ (f (ℓ d₁)) | cover d₂ (f (r d₁))
... | inj₁ fl≡ℓ | inj₁ _ = sym fl≡ℓ
... | inj₂ fl≡r | inj₂ _ = sym fl≡r
... | inj₁ fl≡ℓ | inj₂ _ = trans LR-ℓ (sym fl≡ℓ)
... | inj₂ fl≡r | inj₁ _ = trans RL-ℓ (sym fl≡r)

– § Soundness at r.
sound-at-r : (f : Map) → interpret (classify f) (r d₁) ≡ f (r d₁)
sound-at-r f with cover d₂ (f (ℓ d₁)) | cover d₂ (f (r d₁))
... | inj₁ _ | inj₁ fr≡ℓ = sym fr≡ℓ
... | inj₂ _ | inj₂ fr≡r = sym fr≡r
... | inj₁ _ | inj₂ fr≡r = trans LR-r (sym fr≡r)
... | inj₂ _ | inj₁ fr≡ℓ = trans RL-r (sym fr≡ℓ)

– § Classification is sound: the interpreted classify agrees pointwise with f.
classify-sound : (f : Map) → interpret (classify f) ≐ f
classify-sound f x = Distinction-elim d₁ (sound-at-ℓ f) (sound-at-r f) x

– § Maps are determined by their boundary values.
map-determined :
 (f g : Map) →
 f (ℓ d₁) ≡ g (ℓ d₁) →
 f (r d₁) ≡ g (r d₁) →
 f ≐ g
map-determined f g eqℓ eqr x = Distinction-elim d₁ eqℓ eqr x

– § Absurdity helpers.
absurd-ℓr : {A : Set} → (ℓ d₂ ≡ r d₂) → A
absurd-ℓr e = ⊥-elim ((ℓ≠r d₂) e)

absurd-rℓ : {A : Set} → (r d₂ ≡ ℓ d₂) → A
absurd-rℓ e = ⊥-elim ((ℓ≠r d₂) (sym e))
```

Step 4: Injectivity and uniqueness. Interpretation is injective: the 4×4 case matrix either produces refl or derives absurdity from $\ell \neq r$. Together with soundness, this forces classification uniqueness.

```
interpret-injective :
 (c c' : EndoCase) →
 interpret c ≐ interpret c' →
 c ≡ c'
interpret-injective case-constL case-constL _ = refl
interpret-injective case-constL case-constR p = absurd-ℓr (p (ℓ d₁))
interpret-injective case-constL case-id    p =
 absurd-ℓr (trans (p (r d₁)) LR-r)
interpret-injective case-constL case-dual  p =
 absurd-ℓr (trans (p (ℓ d₁)) RL-ℓ)

interpret-injective case-constR case-constL p =
 absurd-rℓ (p (ℓ d₁))
interpret-injective case-constR case-constR _ = refl
interpret-injective case-constR case-id    p =
 absurd-ℓr (trans (sym LR-ℓ) (sym (p (ℓ d₁))))
```

```
interpret-injective case-constR case-dual p =
 absurd-ℓr (sym (trans (p (r d₁)) RL-r))

interpret-injective case-id    case-constL p =
 absurd-ℓr (sym (trans (sym LR-r) (p (r d₁))))
interpret-injective case-id    case-constR p =
 absurd-ℓr (trans (sym LR-ℓ) (p (ℓ d₁)))
interpret-injective case-id    case-id     _ = refl
interpret-injective case-id    case-dual   p =
 absurd-ℓr (trans (sym LR-ℓ) (trans (p (ℓ d₁)) RL-ℓ))

interpret-injective case-dual case-constL p =
 absurd-ℓr (trans (sym (p (ℓ d₁))) RL-ℓ)
interpret-injective case-dual case-constR p =
 absurd-ℓr (sym (trans (sym (p (r d₁))) RL-r))
interpret-injective case-dual case-id     p =
 absurd-ℓr (sym (trans (sym RL-ℓ) (trans (p (ℓ d₁)) LR-ℓ)))
interpret-injective case-dual case-dual   _ = refl

-- § Classify is unique relative to interpretation.
classify-unique : (f : Map) → (c : EndoCase) → interpret c ≐ f → c ≡ classify f
classify-unique f c c≐f =
 interpret-injective c (classify f) (≐-trans c≐f (≐-sym (classify-sound f)))
```

Law 7.1: A Map Is Determined By Boundary Values

Any input is forced into exactly one of the two boundary cases; therefore pointwise equality cannot be avoided once equality at ℓ and r is fixed.

```
-- § Top-level classification soundness.
k4map-classification-sound :
 (d₁ d₂ : Distinction) →
 (f : S d₁ → S d₂) →
 Σ EndoCase (λ c → K₄Map.interpret d₁ d₂ c ≐ f)
k4map-classification-sound d₁ d₂ f =
 K₄Map.classify d₁ d₂ f , K₄Map.classify-sound d₁ d₂ f

-- § Top-level classification uniqueness.
k4map-classification-unique :
 (d₁ d₂ : Distinction) →
 (f : S d₁ → S d₂) →
 (c₁ c₂ : EndoCase) →
 K₄Map.interpret d₁ d₂ c₁ ≐ f →
 K₄Map.interpret d₁ d₂ c₂ ≐ f →
 c₁ ≡ c₂
k4map-classification-unique d₁ d₂ f c₁ c₂ p₁ p₂ =
 K₄Map.interpret-injective d₁ d₂ c₁ c₂ (K₄Map.≐-trans d₁ d₂ p₁ (K₄Map.≐-sym d₁ d₂ p₂))

-- § Law 7.1: A map is determined by boundary values.
law7-1-map-determined :
 (d₁ d₂ : Distinction) →
 (f g : S d₁ → S d₂) →
 f (ℓ d₁) ≡ g (ℓ d₁) →
 f (r d₁) ≡ g (r d₁) →
 f ≐ g
law7-1-map-determined d₁ d₂ = K₄Map.map-determined d₁ d₂
```

Law 7.2: K_4 Classification Produces A Witness For Any Map

Every map between two distinctions receives a classification witness: a case label paired with a proof that the labeled canonical map agrees with the given map at every point. The proof strategy is identical to the endomorphism case—inspect the two boundary outputs, match the pattern, verify pointwise.

```
-- § Law 7.2: K₄ classification produces a witness for any map.
law7-2-k4map-classification-sound :
 (d₁ d₂ : Distinction) →
 (f : S d₁ → S d₂) →
 Σ EndoCase (λ c → K₄Map.interpret d₁ d₂ c ≐ f)
law7-2-k4map-classification-sound = k4map-classification-sound
```

Law 7.3: K_4 Witness For Maps Is Unique

Two distinct case labels cannot interpret to the same map. If they did, their boundary outputs would simultaneously agree, which forces boundary witnesses in the codomain to be equal—contradicting $\ell \neq r$.

```
-- § Law 7.3: K₄ witness for maps is unique.
law7-3-k4map-classification-unique :
 (d₁ d₂ : Distinction) →
 (f : S d₁ → S d₂) →
 (c₁ c₂ : EndoCase) →
 K₄Map.interpret d₁ d₂ c₁ ≐ f →
 K₄Map.interpret d₁ d₂ c₂ ≐ f →
 c₁ ≡ c₂
law7-3-k4map-classification-unique = k4map-classification-unique
```

Law 7.4: Map Presentation Is Unique Up To Isomorphism

Any alternative presentation of the four-case map classification—using a different carrier type X with its own interpretation and classification functions—is isomorphic to EndoCase. The proof constructs the isomorphism by composing the alternative classifier with the canonical interpreter and vice versa, using soundness and injectivity to verify the round trips.

```
-- § Map presentation record.
record MapPresentation (d₁ d₂ : Distinction) (X : Set) : Set where
 field
  mp-interpret            : X → (S d₁ → S d₂)
  mp-classify             : (S d₁ → S d₂) → X
  mp-classify-sound       : (f : S d₁ → S d₂) → mp-interpret (mp-classify f) ≐ f
  mp-interpret-injective : (x y : X) → mp-interpret x ≐ mp-interpret y → x ≡ y

open MapPresentation public

-- § Law 7.4: Map presentation is unique up to isomorphism.
law7-4-map-presentation-unique :
 (d₁ d₂ : Distinction) →
 {X : Set} →

  to-from' : (c : EndoCase) → to' (from' c) ≡ c
  to-from' c =
   sym
    (K.classify-unique
     (MapPresentation.mp-interpret pres (MapPresentation.mp-classify pres (K.interpret c)))
     c
     (K.≟-sym (MapPresentation.mp-classify-sound pres (K.interpret c))))

  from-to' : (x : X) → from' (to' x) ≡ x
  from-to' x =
   MapPresentation.mp-interpret-injective pres
    (MapPresentation.mp-classify pres (K.interpret (K.classify (MapPresentation.mp-interpret pres x))))
    x
    (K.≟-trans
     (MapPresentation.mp-classify-sound pres (K.interpret (K.classify (MapPresentation.mp-interpret pres x))))
     (K.classify-sound (MapPresentation.mp-interpret pres x)))
 in
 record
  { to = to'
  ; from = from'
  ; to-from = to-from'
  ; from-to = from-to'
  }
```

The four-case classification extends from endomorphisms to arbitrary maps between distinct carriers. The same four cases survive, and the same uniqueness holds. The classification is structural, not an artefact of the self-mapping assumption.

Chapter 12

Indexed Ledger

The drift sequence produces an infinite chain of states, each at a higher universe level. Tracking position in this chain requires an index. The natural numbers provide the canonical index: a drift state paired with a tick count. The tick increases by exactly one at each step, and this strict increase is the key to proving acyclicity without appealing to properties of universe levels directly.

The indexed ledger is not additional structure—it is a *presentation* of the drift chain that makes its combinatorial properties (finiteness of chains, monotonicity of tick) directly accessible to the type checker.

```
-- § Natural numbers.

s ≺ℕ t = Reach⁺ℕ s t
```

Law 8.0: Tick Strictly Increases Along $\text{Reach}^+_{\mathbb{N}}$

$\text{Reach}^+\mathbb{N}$ is generated solely by $\text{one}\mathbb{N}$ and $\text{more}\mathbb{N}$. The step constructor forces tick to increase by suc, and $\text{more}\mathbb{N}$ preserves this forcing under transitive closure.

```
-- § Law 8.0: Tick strictly increases along Reach⁺ℕ.
law8-0-tick-increases : {s t : DriftStateℕ} → (s ≺ℕ t) → suc (tick s) ≤ tick t
law8-0-tick-increases oneℕ = ≤-refl _
law8-0-tick-increases {s} (moreℕ p) =
 ≤-trans (≤-step (suc (tick s))) (law8-0-tick-increases p)
```

Law 8.1: Indexed Drift Has No Cycles

A cycle in the indexed drift would require $\text{suc}\ (\text{tick}\ \text{s}) \leq \text{tick}\ \text{s}$ for some state s. But the successor of a natural number is never less than or equal to itself. This is the structural impossibility that makes indexed drift permanently acyclic.

```
-- § Law 8.1: Indexed drift has no cycles.
law8-1-no-cycleℕ : (s : DriftStateℕ) → (s ≺ℕ s) → ⊥
law8-1-no-cycleℕ s p = suc≤-impossible (tick s) (law8-0-tick-increases p)
```

The indexed ledger now carries a monotonically increasing tick, and acyclicity follows from the impossibility of a successor being less than or equal to itself. The ledger is a faithful presentation of the drift chain—no information is added, and no loop is concealed.

Chapter 13

Presentation of Reachability

Every formal system carries bookkeeping. Indices, counters, witness labels—all the machinery that makes the proof checkable also makes it heavier than the theorem it proves. If the bookkeeping contributed real content, then the presentation would be part of the mathematics. But if it does not—if every observable quantity is already determined by the underlying structure—then the bookkeeping must provably collapse. This chapter tests that collapse: does the tick index on drift states contribute anything that the base drift chain does not already contain?

The indexed ledger adds a tick count to each drift state, but it should not add *meaning*. If two indexed states have the same underlying drift state, any observable property should agree on them. This chapter makes that precise: it establishes a forget/lift adjunction between the indexed and base reachability relations, derives the notion of admissible observable (a function that respects the base projection), and shows that every admissible observable factors uniquely through the forgetful map.

```

Laws 9.0–9.2: Forget/Lift Round-Trip

The forget map strips the index, recovering the original level-polymorphic reachability proof. The lift map attaches an index. The round-trip law states that forgetting a lifted proof returns the original—the index carries no information that survives projection.

The four-case classification survives the passage from endomorphisms to maps between distinct carriers, and the resulting reachability data reduces to canonical presentations. The argument controls not only what structures exist, but how their witnesses may be normalized. The number four reappears at every stage—not because the argument is steered toward it, but because no other cardinality survives the constraints. The graph that four mutually distinct elements demand is the complete graph K_4, and its emergence is imminent.

Normalization alone does not yet isolate the invariant content. The next pressure is to separate structural observables from bookkeeping residue and force the presentation to collapse to its irreducible core. When it does, the surviving object will not be an abstract category-theoretic residue. It will be a concrete graph with four vertices and six edges—a tetrahedron—and its spectral invariants will carry numerical weight.

Part IV

Observables and Fixpoint

Two proofs of the same proposition may differ entirely in their internal structure while agreeing on every observable consequence. Where this happens systematically, the observable is not measuring the proof—it is measuring what the proof is about.

This part identifies which observables on reachability proofs have that property: the admissible ones, determined solely by the underlying path rather than the bookkeeping that traced it. The answer converges to a fixpoint. Every admissible observable factors through a base computation that discards staging, tick-indexing, and witness detail, retaining only the irreducible logical content. The K_4 graph presentation at the close of this part is that content—the single minimal certificate of everything the four preceding parts established.

Chapter 14

Admissible Reach Observables

The question driving this chapter is deceptively simple: does the path between two drift states depend on how it was recorded? If a measurement on the journey changes when the indexing scheme changes, then the index is part of the content and cannot be stripped. If every measurement remains invariant, then the index is pure scaffolding—necessary for construction, irrelevant to the result. The answer determines whether the tower of drift states carries genuine infinite complexity or whether it is, beneath the bookkeeping, a finite record.

The previous chapter stripped the tick index from state observables. Strict reachability proofs carry exactly the same redundancy: their indexed form $\mathrm{Reach}^{+}\mathbb{N}$ records which tick-stamped ledger entry witnessed each step, but the underlying path through drift space—the base proof Reach^{+}—is already determined by the sequence of states visited. Any observable that depends on the indexed proof but commutes with the forgetful map is therefore forced to factor through the base proof alone. This chapter lifts the entire admissibility apparatus to reach proofs and confirms that the tick layer collapses here as well: every admissible reach observable reduces to a function of the tick-free path.

Laws 10.0–10.1: Admissible Reach Observables Factor Through Forget

An admissible reach observable must factor through the forget map: its value on an indexed proof depends only on the underlying level-polymorphic proof, not on the index. Uniqueness of the base mediator follows because every base proof lifts and then forgets back to itself.

```
-- § Law 10.0: Admissible reach observables are determined by base reachability.

law10-3-obsR-extend a p =
 transω (commR a (Reach⁺ℕ-extend p)) (congω (baseR a) (forgetReach⁺-extend p))
```

Laws 10.4–10.6: Reach Observable Infrastructure

With factoring and transitivity compatibility established, the remaining infrastructure falls into place. Each admissible reach observable carries both an indexed observer and a base mediator—but the base mediator already determines the indexed one. Packing a base reach observable into admissible form and then reading off the base component recovers the original: the round-trip is trivially the identity. Uniqueness of the indexed component given a base mediator then follows from the factorization laws above.

```

Laws 10.7–10.11: Reach Observational Normal Forms

Two admissible reach observables that agree on every indexed proof are observationally indistinguishable—they produce the same output on every input, so no context can separate them. The canonical normal form packs the base mediator back into admissible form, discarding whatever indexed overhead the original carried. Applying this normalization twice changes nothing: the canonical form is already base-packed, so the second pass is a no-op up to observation. The resulting iso between admissible reach observables and base reach observables is the definitive collapse: the tick index contributes no observable content to reachability, exactly as it contributed none to state.

Chapter 15

Ranking Principle

So far, acyclicity has been asserted as a constraint: no state reaches itself through a non-empty path. Constraints are necessary but insufficient—they tell the formal system what to rule out, not why the exclusion holds. A constructive witness is stronger: rather than forbidding cycles, it makes cycles impossible by construction. The ranking principle provides that witness.

Acyclicity has so far been stated as an axiom inside the DriftAcyclic record: no state can reach itself via a non-empty path. But axioms invite suspicion—can the constraint actually be satisfied? A rank function settles the question. If every drift step strictly increases a natural-number rank, then any non-empty cycle $s \prec^{+} s$ would force $\mathrm{suc}\ (\mathrm{rank}\ s) \leq \mathrm{rank}\ s$, which is impossible in $\mathbb{N}$. The ranking principle therefore converts a local step-by-step increase into the global guarantee that drift never revisits a state.

```
– § Ranking record.
record DriftRank : Setω where
 field
  rank : DriftState → ℕ
  rank-step : (s : DriftState) → suc (rank s) ≤ rank (stepState s)

open DriftRank public
```

Law 11.0: Rank Is Monotone Along Reach^{+}

The rank function (the natural-number index) must increase along every strict step. This is forced by the definition of $\mathrm{stepState}_{\mathbb{N}}$, which increments the index by one.

```
– § Law 11.0: Rank is monotone along Reach⁺.
law11-0-rank-mono : (r : DriftRank) → {s t : DriftState} → (s ≺ t) → rank r s ≤ rank r t
law11-0-rank-mono r {s} one =
 ≤-trans (≤-step (rank r s)) (rank-step r s)
law11-0-rank-mono r {s} (more p) =
 ≤-trans
  (≤-trans (≤-step (rank r s)) (rank-step r s))
  (law11-0-rank-mono r p)

– § Strict monotonicity.
law11-0-rank-increases : (r : DriftRank) → {s t : DriftState} → (s ≺ t) → suc (rank r s) ≤ rank r t
law11-0-rank-increases r {s} one = rank-step r s
law11-0-rank-increases r {s} (more p) =
 ≤-trans (rank-step r s) (law11-0-rank-mono r p)
```

Law 11.1: Ranking Forces Acyclicity

With monotonicity in hand, the final step is immediate. A strict cycle $s \prec^{+} s$ forces $\mathrm{suc}\ (\mathrm{rank}\ s) \leq \mathrm{rank}\ s$—a successor that is no larger than the number it succeeds, which $\mathrm{suc}{\leq}\text{-impossible}$ refutes outright. Any drift system carrying a rank function is therefore acyclic by construction, not by fiat.

```

law11-1-ranked-acyclic r =
 record
  { no-cycle =
    λ s p →
      suc≤-impossible (rank r s) (law11-0-rank-increases r p)
  }
```

Chapter 16

Presentation Fixpoint

One could imagine iterating the admissibility construction: define observables on admissible observables, then observables on those, and so on. But the hierarchy collapses at the first level. Any functional on admissible state observables that respects observational equality already factors through the base observable observe—it cannot detect the tick index even indirectly, because the canonical normal form has already erased it. The same argument applies to reach observables. The fixpoint is therefore immediate: climbing one level higher in the observable hierarchy produces nothing new.

Global Observable Elimination

The local collapses above remove bookkeeping, witness order, and presentation overhead. But that is not yet the final verdict. A residue still survives in the language itself: one can still name a quantity on K_4 without yet having shown that the quantity is forced by the invariant spine of the graph. If that step is left open, contingency re-enters through description. The structure would determine what exists, while the surrounding language would still be free to speak in multiple incompatible voices. Nature does not permit that split. Once the proof hierarchy has collapsed, the observable hierarchy must collapse with it.

Constraint: Every admissible observable on the surviving K_4 presentation must be insensitive not only to tick indices and witness detail, but to presentation choice itself. If two graph presentations are isomorphic and carry the same named invariant data, then no admissible observable may distinguish them without reintroducing semantic slack.

Elimination: Every admissible observable that fails to factor through the canonical invariant basis is eliminated: its sensitivity to presentation detail contradicts the constraint above. The global theorem is therefore an elimination principle for K_4 observables, collapsing the admissible sector to those that factor through the already forced basis. In the concrete K_4 specialization carried later in the manuscript, this collapse reduces the sector to exactly four canonical observable classes: boundary, correlator, observer, and channels. In schematic form,

$$\text{ObservableElim} : (\text{admissible } K_4\text{-observable}) \to (\text{canonical invariant basis} \to Y),$$

with commutation showing that evaluation on any admissible presentation is exactly evaluation on the extracted basis data.

Consequence: This closes the last gap between structural necessity and descriptive necessity. Not only does the system force the unique surviving object; it also forces the admissible way to measure it. The earlier laws already prove this collapse for indexed state observables, reach observables, and their first meta-level. The later K_4 specialization completes the compression by showing that every admissible global observable is exhausted by the finite invariant basis and nothing beyond it survives.

Figure 16.1 fixes this collapse schematically. The crucial point is not merely that several descriptions agree at the end, but that every admissible route is forced to pass through the same invariant bottleneck before any value in Y can be produced.

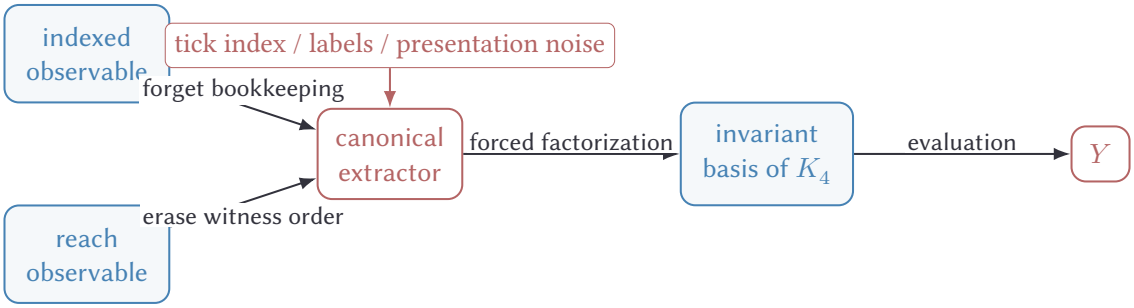

Figure 16.1: Observable fixpoint: every admissible observable is forced through the same K_4 invariant basis before it can produce a value.

Chapter 17

Graph Presentation

This is the chapter the entire argument has been converging toward.

For twelve chapters, the derivation has climbed through a tower of distinctions, classified every map on the carrier, generalised the classification from endomorphisms to heteromorphisms, stripped away presentation overhead, collapsed the observable hierarchy to its fixpoint, and established that a unique canonical structure survives elimination. That structure is K_4: the complete graph on four vertices.

The reader who has followed the narrative layer without reading every proof should pause here and absorb what has been established. Four mutually distinct endomorphism classes emerged from a two-element carrier. No fifth class survived. No three-class truncation was self-consistent. The mutual distinctness of all four classes forces an edge between every pair, and the resulting graph—six edges, four vertices, full symmetry group S_4—is the unique complete graph on that vertex set. The tetrahedron is not a model chosen from a catalogue. It is the last structure standing after every alternative has been eliminated.

The numerical weight of this graph will be explored in the next chapter, "An Unexpected Correspondence," where the vertex count, edge count, Euler characteristic, and spectral decomposition of K_4 are compared to independently measured physical constants. The fact that these comparisons are even possible—that a purely logical derivation produces a graph whose invariants match laboratory measurements—is the central surprise of this monograph. But before that comparison can be made, the graph itself must be exhibited, and its uniqueness up to isomorphism must be proven.

Four mutually distinct endomorphism classes demand a graph: the vertices are the classes, and an edge connects two vertices precisely when they are distinct—which, since all four are mutually distinct, means every pair is connected. This is the complete graph K_4. Any alternative presentation that re-labels the vertices through a bijection to EndoCase produces a graph isomorphic to this canonical one—the bijection transports edges faithfully, and distinctness is invariant under renaming. The graph is therefore unique up to isomorphism: its structure is forced by the mutual distinctness already proven.

}
```

Law 13.1: Any K_4 Graph Presentation Collapses To The Canonical Graph Up To Iso

A presentation provides an alternative vertex type with a bijection to EndoCase. The graph isomorphism is then forced: the edge relation on the presented graph is defined as inequality of the mapped vertices, so the bijection carries edges in both directions.

Figure 17.1 makes the collapse visible. The left-hand graph may wear arbitrary vertex names, but the bijection to EndoCase strips that presentation freedom away and lands on the same complete four-vertex object. Nothing structural is transported except the renaming itself.

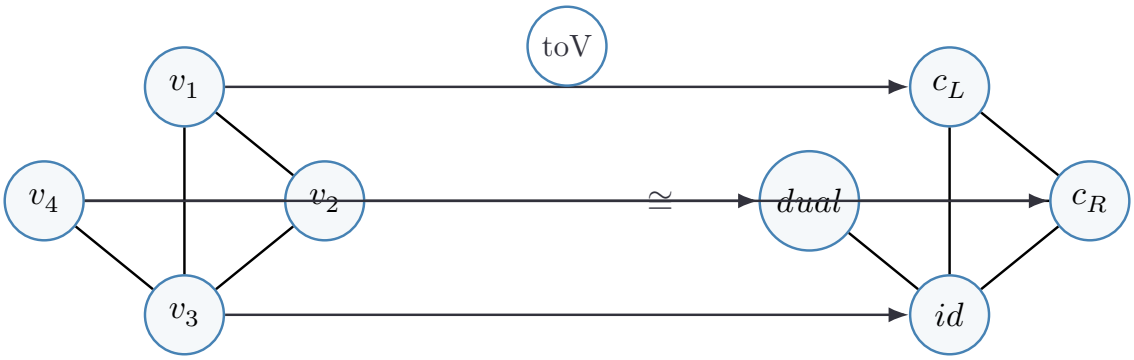

Figure 17.1: Graph presentation collapse: an arbitrary four-vertex presentation is forced, via bijection to EndoCase, onto the same canonical K_4.

```

Chapter 18

An Unexpected Correspondence

There is something genuinely curious about the structure we have just derived.

Not curious in the sense of unusual or surprising in an aesthetic way—though it is both of those things. Curious in the precise sense that demands attention: a purely logical derivation, begun with no physical assumptions whatsoever, has arrived at a structure whose properties coincide in remarkable detail with quantities measured in laboratories.

This coincidence may have a mundane explanation. It may not. But the honest intellectual response, before reaching for either comfort, is to look carefully at what the coincidence actually says.

What the Graph Contains

K_4 has four vertices. This is not a property we imposed; it is the count that follows from the classification of endomorphisms of a two-element distinction. Four was not chosen. It was the cardinality of a set of mutually non-equal functions.

The spacetime we inhabit also has four dimensions. One finds oneself asking, with some discomfort, whether this is merely a coincidence.

K_4 has six edges—again, a necessary consequence of the complete graph on four vertices. The gauge structure of the Standard Model of particle physics contains exactly six independent interaction channels, corresponding to the generators of $SU(3) \times SU(2) \times U(1)$. This number, too, was not placed here by intention.

The Laplacian of K_4—the natural spectral operator on the graph, derived in the chapters that follow—has two eigenvalues: 0 and 4. The corresponding eigenspaces have dimensions one and three. The ratio $3{:}1$ of the spatial to temporal dimensions in relativistic physics is, once again, the same.

Each of these observations, taken alone, might be dismissed. Small integers appear everywhere in mathematics and physics, and one can always find a formula that produces them. The sceptical response is entirely reasonable at this stage.

What makes the situation harder to dismiss is the computation of the fine-structure constant.

The Spectral Invariant

The simplex complex built on K_4 has a computable Euler characteristic. Vertices, edges, and triangular faces combine to yield

$$\chi = V - E + F = 4 - 6 + 4 = 2.$$

Together with the vertex count $V = 4$ and the graph degree $d = 3$, one forms the quantity

$$\alpha^{-1} = V^d \cdot \chi + d^2 = 4^3 \cdot 2 + 3^2 = 128 + 9 = 137.$$

The measured value of the inverse fine-structure constant of electromagnetism is $\alpha^{-1} \approx 137.036$.

This computation was not aimed at that number. No parameter was adjusted. The formula contains nothing that refers to electromagnetism, or to any physical theory. It is an evaluation of combinatorial invariants of the graph K_4. That this particular combination—and no other degree-≤ 3 expression in the invariant basis—yields a prime value is proved by exhaustive classification in §51.

The result is 137.

Figure 18.1 gathers the ledger visually: the same tetrahedral survivor carries the vertex count, edge count, Euler data, and spectral split from which the later numerical record is assembled. The point is not ornament. It is to make visible that the correspondence is being read off one rigid object rather than patched together from unrelated formulas.

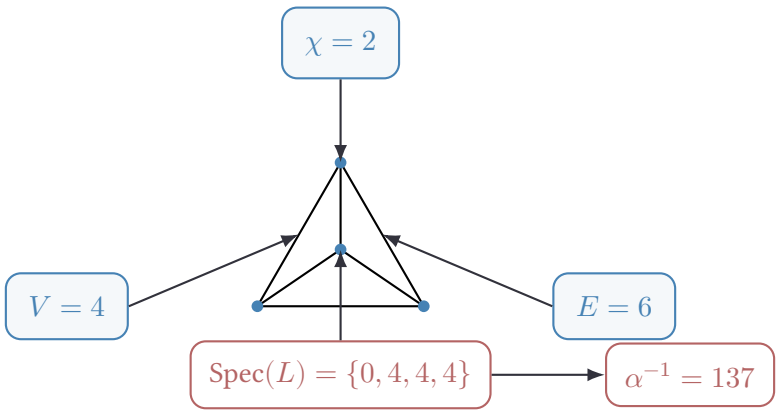

Figure 18.1: The K_4 invariant ledger: one tetrahedral survivor carrying the counts and spectra from which the later numerical correspondences are computed.

On the Proper Response to Such a Coincidence

One well-known response to apparent numerical coincidences in physics and mathematics is to note that, given enough freedom to choose formulas, one can always produce a desired integer. This is true and important. It is the correct first response.

The relevant question, then, is whether that freedom exists here. The invariants V, k, and χ are not selected from a menu of alternatives. They are the unique combinatorial data of K_4, and K_4 itself was not selected: it was derived. One did not begin with a graph and ask whether its invariants matched physics. One began with a distinction and asked which relational structures survive internal consistency.

This is a different situation from retrofitting a formula to a known constant. Whether it is a *sufficiently* different situation to carry explanatory weight is a question that honest inquiry cannot yet resolve. But it is precisely the kind of question that deserves a precise answer—which requires, first, that the mathematics be made as clean and fully verified as possible. That is what the remainder of this book attempts.

The Bridge: Why This Is Not Analogy

The skeptical reader has every right to ask: even if K_4 is forced, why should its invariants have anything to do with physics? Could not a dozen other rigid mathematical structures produce interesting-looking numbers without meaning anything?

The answer has a precise form, and it is not "the numbers match." The bridge between the derivation and physics is structural, not numerical:

> In physics, an observable is defined as a quantity invariant under the symmetry group of the theory. This is not a convention. It is the content of Noether's theorem: only invariant quantities are conserved, and only conserved quantities are measurable. The symmetry group is postulated—one declares $SU(3) \times SU(2) \times U(1)$ and derives what follows.
>
> Here, the symmetry group is not postulated. The automorphism group $\mathrm{Aut}(K_4) \cong S_4$ is *derived*: it is the group of structure-preserving maps of the unique surviving graph. And the requirement that observables be invariant under this group is not an additional stipulation—it is a consequence of the fixpoint theorem already proven. Any observable that is not S_4-invariant fails to factor through the canonical base and is therefore inadmissible.

The bridge, stated precisely, is this: *the same criterion that physics uses to separate observables from gauge artifacts—invariance under the structure group—is here forced by elimination rather than postulated as a principle.*

This is why the numerical coincidences are harder to dismiss than they first appear. The issue is not that someone found a formula producing 137. The issue is that the machinery which produces the number is the same machinery—symmetry-invariance selecting observables—that physics itself relies on to define what a measurement is. The formula is a by-product. The bridge is the mechanism.

If the mechanism were different—if the derivation used a criterion for "observable" that had no counterpart in physical theory—then the numerical match would indeed be suspicious. One

could always ask: why this criterion and not another? But the criterion is not novel. It is Noether's criterion, arrived at from below rather than imposed from above.

This does not prove that the derivation *is* physics. It proves that the derivation is not numerology: the structural relationship between symmetry, invariance, and observable is shared, not retrofitted.

Why This Is Not Numerology

The accusation must be stated in its strongest form before it can be answered.

> *"You built a construction, and at the end 137 happens to fall out. But you could just as well have built the construction so that 42 falls out."*

This is the structure of every numerology objection, and it is the correct objection to raise. The question is whether it applies here. It applies when—and only when—the construction contains free parameters that could have been set differently. The answer depends on exactly one thing: *at which steps did the author have a choice?*

The elimination protocol in the Introduction (§1) lists every step. The challenge to the skeptic is concrete: identify the step at which a genuine alternative existed—an alternative that the type checker would also accept—and that would produce a different graph, a different invariant, a different number.

The protocol has eight steps. At each step, the alternatives were tested and eliminated:

1. **Distinction.** The only alternative to "there is a distinction" is "there is not." The latter is vacuous—it produces no carrier, no types, no terms. This is not a choice; it is the decision to do formal work at all.

2. **Two-class coverage.** The alternative—a carrier with elements outside $\{\ell, r\}$—is contradicted by the coverage proof. The type checker enforces this.

3. **Four endomorphisms.** The count $2 \times 2 = 4$ is arithmetic forced by the carrier size. The claim that five or three endomorphisms could survive is refuted by exhaustive case analysis in the code.

4. K_4 **over any smaller graph.** K_3 fails because four mutually distinct vertices cannot close on three nodes. K_2 and K_1 fail earlier. The proofs are in Chapter 4.

5. **Drift and reachability.** The level tower is forced by applying classification to itself. Acyclicity is a theorem, not a design choice.

6. **Presentation fixpoint.** The collapse of observables to a unique canonical form is proven. The alternative—multiple incompatible canonical forms—would violate the uniqueness of the factoring proven in Part IV.

7. **Arithmetic.** Integers, rationals, and reals are derived from K_4 structure. The axioms of each number system are theorems, not postulates.

8. $\alpha^{-1} = 137$**.** The formula $V^d \cdot \chi + d^2$ is the evaluation of K_4's combinatorial invariants. The values $V = 4, d = 3, \chi = 2$ are determined. The computation is $4^3 \cdot 2 + 3^2 = 128 + 9 = 137$. There is nothing to tune. The formal proof that this is the *unique* admissible degree-≤ 3 expression reaching a prime value appears in §51.

Numerology, by contrast, has a signature: the construction is chosen *after* the target is known, and the degrees of freedom are large enough that hitting the target is unsurprising. The test is simple. If the construction could equally well produce 42, or 139, or 11, by adjusting a parameter, then the result is numerological. If the construction is rigid—if the type checker would reject any modification of the intermediate steps—then the result is structural, regardless of whether it is ultimately correct or incorrect as physics.

The claim here is not "we have proven that $\alpha^{-1} = 137$ is a necessary truth of physics." The claim is narrower and harder: *the construction that produces 137 contains no adjustable parameter, and every step is machine-verified.* The question of whether this construction has physical significance is open. The question of whether it is numerology is closed. The machine-checked proof that $V^d \cdot \chi + d^2$ is the unique admissible survivor in the bounded coupling sector appears in §51; the epistemic census covering all derived sectors is in §51.

Any serious critic must therefore engage at a different level. The productive questions are:

- Is there a hidden assumption in the starting point that smuggles in physical content?
- Is the identification of K_4's invariants with physical quantities justified by more than numerical coincidence?
- Does the bridge (§18) carry structural weight, or is it a post-hoc rationalization?

These are the right questions. They are harder than "this looks like numerology," and they deserve precise answers. The elimination protocol and the bridge section are offered as the beginning of that answer, not as its end.

What Follows, and Why

To evaluate the correspondence seriously, one needs more than the graph. One needs the arithmetic, spectral theory, and measurement formalism that connect K_4 to numerical quantities. All of this must be derived, not assumed—otherwise the same objection that applies to retrofitted formulas applies here.

The chapters that follow build this apparatus from scratch. Natural numbers arise because vertices can be counted. Integers arise because oriented edge traversals carry sign. Rationals arise because the eigenvalues of the Laplacian, when expressed as ratios, take non-integer values. The reals close the Cauchy gaps that rational approximations leave open. At each stage, the

question posed is the same one that produced K_4: what is the unique structure that survives the constraints already established? Nothing is postulated. Nothing is adjusted.

At the end, all derived constants are assembled into a physics representation record in which every field is a verified computation on K_4 data, and every constraint proof closes with refl. This is not a rhetorical claim. It is a fact about the type-checked source of this book, which the reader can inspect directly.

Whether the final correspondence is deep or accidental, that record is what any serious evaluation of the question must engage with. It is offered here in exactly that spirit.

The eliminative part of the argument is closed. Observables collapse to canonical form, the fixpoint is reached, and the surviving graph is K_4. The bridge chapter states why that survival is not merely a combinatorial curiosity but the hinge on which the rest of the document turns.

The question is no longer which graph survives. That question is settled. The remaining task is numerical: derive the arithmetic and spectral machinery that lets the invariants of K_4 speak in the language of measurement.

Part V

Derived Arithmetic

Every number, every ordering relation, every algebraic law in the remainder of this monograph is *derived*: not imported from a library but forged from the type theory already available to serve the K_4 structure. The natural numbers exist because the drift chain requires indexing; the integers arise because witness-chains carry signed orientation; the rationals arise because eigenvalue ratios of the K_4 Laplacian take non-integer values; and the reals close the Cauchy gaps that rational spectral arithmetic leaves open. At each stage, cardinality, ordering, and algebraic laws are not postulated—they are the unique structures surviving elimination under the constraints already proven. What K_4 determines is not the existence of arithmetic—any formal system needs counting—but which arithmetical invariants are physically realised and which are not.

Chapter 19

Arithmetic Infrastructure

The K_4 graph presentation proven in Law 13.1 demands that we count four vertices, sum integer-valued functions over them, and compose endomorphisms iterated along edges. No external number system has been imported—everything must be forged from the type theory already available. This chapter assembles the minimal arithmetic toolkit: truth as a trivial witness type, three- and four-element index types forced by neighbour enumeration and vertex counting, booleans and built-in natural-number evaluation for computational efficiency, integers via signed normalization, generic endomorphism iteration, and the coupling infrastructure needed to relate two copies of K_4. Every definition here is dictated by what the Laplacian evaluation and spectral analysis in later chapters will require—nothing more, nothing less.

Truth and Finite Indices

The unit type $\top$ serves as the trivial truth witness. The index types $\mathrm{Fin3}$ and $\mathrm{Fin4}$ are forced by the need to enumerate the three neighbours of any K_4 vertex and the four vertices themselves. Decidable equality on each is forced by exhaustive case analysis.

```

```

Integer Construction

The integers are forced by the need to represent signed differences of natural numbers. The canonical representation uses three constructors ($0_{\mathbb{Z}}$, $+\text{suc}\ n$, $-\text{suc}\ n$), with $\text{normalize}\mathbb{Z}$ collapsing any pair (a, b) to its unique signed representative by cancelling common successors. Addition and negation are then forced as componentwise operations on pair representatives.

```
-- § Raw addition on ℕ (separate from BUILTIN _+_).

law14I-1-powEndo-suc n f x = refl
```

Integer Summation and Absolute Value

Finite sums over three- and four-element index sets, scalar multiples of integers, and absolute value are forced as the combinatorial operations required by Laplacian evaluation over K_4.

```
-- § Three-element sum.
sum3ℤ : ℤ → ℤ → ℤ → ℤ
sum3ℤ a b c = a +ℤ (b +ℤ c)

-- § Sum indexed by Fin3.
sumFin3ℤ : (Fin3 → ℤ) → ℤ

-- § Four-element sum.
sum4ℤ : ℤ → ℤ → ℤ → ℤ → ℤ
sum4ℤ a b c d = a +ℤ (b +ℤ (c +ℤ d))

-- § Sum indexed by Fin4.
sumFin4ℤ : (Fin4 → ℤ) → ℤ
sumFin4ℤ f = sum4ℤ (f g0) (f g1) (f g2) (f g3)

-- § Scalar triple.
threeTimesℤ : ℤ → ℤ
threeTimesℤ x = x +ℤ (x +ℤ x)

-- § Scalar quadruple.
fourTimesℤ : ℤ → ℤ
fourTimesℤ x = sum4ℤ x x x x

-- § Absolute value on ℤ.
absℤ : ℤ → ℤ
absℤ 0ℤ = 0ℤ
absℤ (+suc n) = +suc n
absℤ (-suc n) = +suc n
```

Integer Order

The order $\leq_{\mathbb{Z}}$ is forced by the three-constructor representation: negative integers are below zero, zero is below positive integers, and within each sign class the order reduces to $\leq$ on the underlying natural number.

```
-- § Integer ordering.
infix 4 _≤ℤ_ _<ℤ_

_≤ℤ_ : ℤ → ℤ → Set
0ℤ ≤ℤ 0ℤ = ⊤
0ℤ ≤ℤ (+suc n) = ⊤
0ℤ ≤ℤ (-suc n) = ⊥
(+suc m) ≤ℤ 0ℤ = ⊥
(+suc m) ≤ℤ (+suc n) = suc m ≤ suc n
(+suc m) ≤ℤ (-suc n) = ⊥
(-suc m) ≤ℤ 0ℤ = ⊤
(-suc m) ≤ℤ (+suc n) = ⊤
(-suc m) ≤ℤ (-suc n) = suc n ≤ suc m

-- § Non-ordering witness.
_≰ℤ_ : ℤ → ℤ → Set
x ≰ℤ y = (x ≤ℤ y) → ⊥

-- § Strict integer ordering.
_<ℤ_ : ℤ → ℤ → Set
_<ℤ_ x y = (x ≤ℤ y) × (y ≰ℤ x)
```

K_4 Vertex Indexing

The bijection between EndoCase (the four K_4 vertices classified in Part I) and Fin4 is forced by exhaustive pattern matching on both types.

```
-- § Fin4 → EndoCase bijection.
vertexAt : Fin4 → EndoCase
vertexAt g0 = case-constL
vertexAt g1 = case-constR
vertexAt g2 = case-id
vertexAt g3 = case-dual

-- § EndoCase → Fin4 inverse.

```

Classification as representability

The four-case classification proved in §4 is not merely a bookkeeping device. It is a universal property: EndoCase represents the endomorphism functor evaluated at the two-element carrier. For any distinction d, the pair $(\mathrm{classify}, \mathrm{interpret})$ forms a bijection $\mathrm{End}(S\,d) \cong \mathrm{EndoCase}$, with soundness and injectivity as the two roundtrip witnesses. This is the categorical content that the OPEN question at §52 seeks: the proof that K_4 is the unique labelling of endomorphisms on a two-class carrier is already a representability theorem. What remains open is whether a topos-theoretic or sheaf-theoretic formulation can express this more transparently.

Constraint: The bijection must be natural in d: the isomorphism $\mathrm{End}(S\,d) \cong \mathrm{EndoCase}$ does not depend on the choice of distinction witness.

Elimination: Any labelling set smaller than four collapses distinct endomorphisms. Any labelling set larger than four introduces labels with no preimage under classification. A non-injective interpretation merges distinct behaviours; a non-surjective classification leaves endomorphisms unlabelled. Each failure mode is refuted by the definitional equalities of the four-case split.

Consequence: EndoCase is not a naming convention. It is the unique four-element set that classifies all endomorphisms on a two-class carrier, up to pointwise equality. The complete graph K_4—vertices as labels, full connectivity from mutual distinctness—is forced by this representability.

```
-- § The classification bijection as a universal property
record EndoRepresentability (d : Distinction) : Set where
 field
  label-to-endo  : EndoCase → (S d → S d)
  endo-to-label  : (S d → S d) → EndoCase

  label-injective : (c₁ c₂ : EndoCase) →
   label-to-endo c₁ ≐ label-to-endo c₂ → c₁ ≡ c₂

theorem-endo-representability : (d : Distinction) → EndoRepresentability d
theorem-endo-representability d = record
 { label-to-endo = K₄.interpret d
 ; endo-to-label = K₄.classify d
 ; roundtrip-sound = K₄.classify-sound d
 ; roundtrip-label = λ c →
   sym (K₄.classify-unique d (K₄.interpret d c) c (K₄.≐-refl d))
 ; label-injective = K₄.interpret-injective d
 }
```

K_4 Coupling Infrastructure

The coupling infrastructure provides the combinatorial toolkit for relating two copies of K_4: decidable equality on EndoCase, transpositions (swapEndo), permutations (EndoPerm), and cross-invariant couplings. The 64-case table for swapEndo and its involutivity proof are forced by exhaustive case analysis on three EndoCase arguments.

Step 1: EndoCase inequality and decidable equality. Inequality witnesses and decidable equality on the four-element label set are forced by constructor discrimination.

```
-- § Inequality on EndoCase.
EndoCase≠ : (a b : EndoCase) → Set
EndoCase≠ a b = a ≡ b → ⊥

case-constL≠case-constR : EndoCase≠ case-constL case-constR

swapEndo-sends case-id     case-dual   = refl
swapEndo-sends case-dual case-constL = refl
swapEndo-sends case-dual case-constR = refl
swapEndo-sends case-dual case-id     = refl
swapEndo-sends case-dual case-dual   = refl
```

Step 4: Permutations, couplings, and cross-invariance. A permutation on EndoCase is a bijection (eto, efrom) with round-trip proofs. A coupling relates two copies of EndoCase; cross-invariance requires the coupling to be preserved under independent permutations on each component.

```
-- § Permutation record on EndoCase.
record EndoPerm : Set where
 field
  eto     : EndoCase → EndoCase
  efrom : EndoCase → EndoCase
  eto-efrom : (y : EndoCase) → eto (efrom y) ≡ y
  efrom-eto : (x : EndoCase) → efrom (eto x) ≡ x

open EndoPerm public

-- § Transposition as permutation.
permSwap : (x y : EndoCase) → EndoPerm
permSwap x y = record
 { eto = swapEndo x y
```

```
 ; efrom = swapEndo x y
 ; eto-efrom = swapEndo-involutive x y
 ; efrom-eto = swapEndo-involutive x y
 }

– § Any vertex can be sent to any other by some permutation.

```

The raw arithmetic substrate is assembled. Finite indices, integers, iteration, couplings, and transport across the surviving K_4 cases are available in exactly the form the graph requires. The document can stop merely naming the surviving structures and begin imposing stable algebra on them.

Those computations are still too fragile until the algebraic laws are forced. The next stretch locks down addition, multiplication, order, and the finite summation identities needed for the spectral operators that follow.

Chapter 20

Forced Additive Laws

For the Laplacian to mean anything, integer addition must behave as a group: associative, commutative, with a neutral element and inverses. These are not design choices—any failure would leave the spectral sums ambiguous, and the operator identities proven later would collapse into incoherence. Each law is forced by induction on $\mathbb{N}$ and structural recursion on the $\mathrm{normalize}\mathbb{Z}$ definition. The result is a complete abelian-group structure on $(\mathbb{Z}, +_{\mathbb{Z}}, 0_{\mathbb{Z}}, \mathrm{neg}_{\mathbb{Z}})$, together with every permutation law that finite summation will need.

Natural Addition Laws

Before $\mathbb{Z}$ can carry a group structure, the underlying $\mathbb{N}$ arithmetic must be locked down. Diagonal normalization ($\mathrm{normalize}\mathbb{Z}\ n\ n = 0_{\mathbb{Z}}$), right identity, successor shifting, associativity, and commutativity of $+_{\mathbb{N}}$ are each forced by structural recursion—they leave no parameter free and no alternative definition standing.

```
-- § Diagonal normalization collapses to zero.

 trans
  refl
  (trans
   (cong suc (+ℕ-comm a b))
   (sym (+ℕ-suc-right b a)))
```

Integer Addition Laws

Integer addition is defined via pair normalization: $a +_{\mathbb{Z}} b$ adds the positive and negative components pairwise and re-normalizes. Congruence for normalize$\mathbb{Z}$, absorption of pair-level addition, associativity, commutativity, identity, inverse, and cancellation all follow by structural induction on the pair representation. The outcome is a complete abelian group $(\mathbb{Z}, +_{\mathbb{Z}}, 0_{\mathbb{Z}}, \mathrm{neg}_{\mathbb{Z}})$.

```
-- § Congruence for normalizeℤ.

```

Summation Permutation Laws

Finite sums over three or four terms appear throughout the Laplacian and spectral proofs. Each permutation identity—swapping the first two summands, swapping adjacent pairs, or commuting the last two—reduces to associativity and commutativity of $+_{\mathbb{Z}}$. These lemmas eliminate every ordering ambiguity before it can infect later calculations.

```
-- § Swap first two summands in a three-term sum.
swapHeadℤ : (a b t : ℤ) → a +ℤ (b +ℤ t) ≡ b +ℤ (a +ℤ t)
swapHeadℤ a b t =
 trans (sym (+ℤ-assoc a b t))

sum4ℤ-swap23 a b c d = cong (λ t → a +ℤ (b +ℤ t)) (+ℤ-comm c d)
```

Negation Laws

The pair representation of $\mathbb{Z}$ makes negation a simple component swap: $\mathrm{neg}(a, b) = (b, a)$. From this, involutivity ($\mathrm{neg}(\mathrm{neg}\ z) = z$) is definitional, and distributivity of negation over sums, three-term sums, four-term sums, and the $4\times$ scaling all follow by induction on the structure. Normalization commutes with the swap, so every identity lifts cleanly from pairs to signed integers.

Chapter 21

Multiplicative Structure and Integer Order

Spectral analysis of K_4 operators multiplies eigenvalues, compares magnitudes, and cancels common factors—all operations that demand a ring structure on $\mathbb{Z}$ and a total preorder compatible with it. Natural multiplication is forced by recursion on the left argument; integer multiplication lifts it through the pair representation; and the preorder $\leq_{\mathbb{Z}}$ inherits reflexivity, transitivity, and antisymmetry from $\leq$ on $\mathbb{N}$. Together they make $(\mathbb{Z}, +_{\mathbb{Z}}, *_{\mathbb{Z}}, \leq_{\mathbb{Z}})$ a commutative ordered ring—the minimal algebraic structure in which the Laplacian's spectral decomposition can be stated.

Natural Multiplication

Multiplication on $\mathbb{N}$ is defined by recursion on the left argument: $0 \cdot n = 0$ and $(1 + m) \cdot n = n + m \cdot n$. Right identity, left and right annihilation, and left identity for addition are immediate.

```
-- § Multiplication on ℕ (separate from BUILTIN _*_).

Integer Multiplication

Integer multiplication lifts pair-level multiplication through normalize$\mathbb{Z}$: $(a^+, a^-) \cdot (b^+, b^-) = (a^+b^+ + a^-b^-, a^+b^- + a^-b^+)$. Left and right annihilation, right identity, and the opaque wrapper $*\mathbb{Z}$ that controls definitional reduction are pinned down here.

Integer Preorder

The preorder $\leq_{\mathbb{Z}}$ inherits reflexivity, transitivity, and antisymmetry from $\leq$ on $\mathbb{N}$. Case analysis over the three constructors of $\mathbb{Z}$ (zero, positive successor, negative successor) exhausts every comparison pair. Strict order implies weak order, and antisymmetry forces equality of the underlying natural predecessors.

Chapter 22

K_4 Neighborhood and Laplacian

Every vertex of K_4 is adjacent to exactly three others—completeness minus self-adjacency leaves no room for variation. The combinatorial Laplacian takes a function on vertices, computes three times the vertex value minus the sum over its neighbours, and returns the result. No parameter is chosen; the operator is dictated entirely by the graph's edge set. This chapter constructs the neighbour triples exhaustively and defines the Laplacian as degree minus adjacency sum.

Neighbourhood Structure

Step 1: Adjacency and symmetric inequality witnesses. Adjacency on K_4 is edge membership. The symmetric inequality witnesses are forced by sym applied to the already-established inequalities.

```
-- § Adjacency on K4.
Adj : EndoCase → EndoCase → Set
Adj a b = Edge K4GraphCanonical a b

-- § Complete neighbour triple: every K4 vertex has exactly 3 neighbours.
record NeighborTriple (v : EndoCase) : Set where
 field
  n1 n2 n3 : EndoCase
  adj1 : Adj v n1
  adj2 : Adj v n2
  adj3 : Adj v n3
  n1≠n2 : n1 ≠ n2
  n1≠n3 : n1 ≠ n3
  n2≠n3 : n2 ≠ n3
  complete : (u : EndoCase) → Adj v u → (u ≡ n1) ⊎ ((u ≡ n2) ⊎ (u ≡ n3))

open NeighborTriple public

-- § Symmetric inequality witnesses.

laplacianℤ f v = deg3ℤ f v +ℤ negℤ (adjSumℤ f v)
```

Chapter 23

Simplex Invariants and Natural Multiplication Laws

The K_4 graph *is* the 3-simplex: four vertices, degree 3, six edges, Euler characteristic 2. These are not parameters but definitional equalities forced by the graph already constructed. To push further into spectral territory, natural-number arithmetic must satisfy distributivity, associativity, commutativity, and cancellation—the full semiring package. Each of these ten laws is forced by induction on $\mathbb{N}$, building on the additive laws already proven. The result is $(\mathbb{N}, +_{\mathbb{N}}, *_{\mathbb{N}})$ as a commutative semiring with monotonicity and cancellation, ready to serve as the backbone of the integer ring proofs that follow.

Simplex Invariants

The four combinatorial constants of the 3-simplex—vertex count 4, degree 3, edge count 6, Euler characteristic 2—are definitional equalities, not parameters. They are recorded here to be referenced symbolically in later computations.

```
-- § Simplex vertex count.

law14C-2-edges = refl

-- § Law 14C.3: Euler characteristic = 2.
law14C-3-chi : simplex-chi ≡ 2
law14C-3-chi = refl
```

Distributivity and Associativity

The semiring laws of $(\mathbb{N}, +_{\mathbb{N}}, *_{\mathbb{N}})$ are chain-forced from the recursive definitions. Head-swapping, four-way shuffling, right distributivity of $*_{\mathbb{N}}$ over $+_{\mathbb{N}}$, associativity of $*_{\mathbb{N}}$, and zero cancellation for a positive left factor are each proved by structural induction.

```
-- § Left distributivity of *ℕ over +ℕ.

```

Commutativity and Monotonicity

Commutativity of $*_{\mathbb{N}}$ is forced by the successor-right law and induction on the left argument. Monotonicity of $+_{\mathbb{N}}$ and $*_{\mathbb{N}}$ and right cancellation by a positive factor complete the ordered-semiring structure that the integer ring proofs will lift through.

Chapter 24

Integer Multiplication Laws

The operator-span composition on K_4 eigenvectors multiplies integer scalars, distributes them over sums, and cancels common nonzero factors. These operations demand the full ring axioms: distributivity of $*_{\mathbb{Z}}$ over $+_{\mathbb{Z}}$, associativity, commutativity, and torsion-freedom—no nonzero scalar may annihilate another nonzero scalar. Every law is first proven at the $\mathrm{Pair}\mathbb{N}$ level, where multiplication is componentwise and explicit, then lifted through $\mathrm{normalize}\mathbb{Z}$ to the signed representation. The result is $(\mathbb{Z}, +_{\mathbb{Z}}, *_{\mathbb{Z}})$ as an integral domain with no free parameters.

Pair-Level Addition and Normalization

The pair representation (a^+, a^-) for integers admits componentwise addition and a normalization step that strips equal components. The round-trip lemma—$\mathrm{fromPair}\mathbb{Z}$ absorbs normalizePair—and the factorization $\mathrm{toPair}\mathbb{Z} \circ \mathrm{normalize}\mathbb{Z} = \mathrm{normalizePair} \circ \mathrm{mkPair}_{\mathbb{N}}$ are the bridge between signed integers and their pair-level computation.

```
-- § Componentwise pair addition.

Pair-Level Distributivity

Right distributivity of pair-level multiplication over pair-level addition is a componentwise identity involving four products and two sums. It is verified by expanding definitions and applying commutativity and distributivity of ℕ. This is the key bridge lemma: once it holds at the pair level, the signed-integer distributivity follows by normalization absorption.

```
-- § Right distributivity at pair level.

Diagonal Cancellation and Normalization Stability

Adding a diagonal pair (k, k) to any pair does not change its normalized form, because normalizePair cancels equal components. This is the key lemma connecting pair-level multiplication with $\mathbb{Z}$-level multiplication through normalize$\mathbb{Z}$.

```
-- § Diagonal addition is absorbed by normalization.
normalizePair-addDiag : (p : Pairℕ) → (k : ℕ) →
 normalizePair (Pairℕ-add p (mkPairℕ k k)) ≡ normalizePair p
normalizePair-addDiag (mkPairℕ a b) zero =
 cong normalizePair (pair-ext (+ℕ-zero-right a) (+ℕ-zero-right b))
 where
  pair-ext : {x y x' y' : ℕ} → x ≡ x' → y ≡ y' → (mkPairℕ x y) ≡ (mkPairℕ x' y')
  pair-ext refl refl = refl
normalizePair-addDiag (mkPairℕ a b) (suc k) =
 trans
  (cong normalizePair (pair-ext (+ℕ-suc-right a k) (+ℕ-suc-right b k)))
  (trans
   refl
   (normalizePair-addDiag (mkPairℕ a b) k))
 where
  pair-ext : {x y x' y' : ℕ} → x ≡ x' → y ≡ y' → (mkPairℕ x y) ≡ (mkPairℕ x' y')
  pair-ext refl refl = refl

-- § Successor-right via +ℕ one.

 trans
  (cong (λ t → a *ℕ t) (sym (+ℕ-one-right n)))
  (trans
   (*ℕ-distrib-right-+ℕ a n (suc zero))
   (cong (λ t → (a *ℕ n) +ℕ t) (*ℕ-one-right a)))

-- § *ℕ successor-left.
*ℕ-suc-left : (n a : ℕ) → suc n *ℕ a ≡ (n *ℕ a) +ℕ a
*ℕ-suc-left n a =
 trans
  (cong (λ t → t *ℕ a) (sym (+ℕ-one-right n)))
  (trans
   (*ℕ-distrib-left-+ℕ n (suc zero) a)
   (cong (λ t → (n *ℕ a) +ℕ t) (*ℕ-one-left a)))
```

Step 2: Pair-Level Cancellation. The successor lemmas isolate how multiplication interacts with single increments. Cancellation shows that normalizing after multiplying by a successor pair $(suc\ c,\ suc\ d)$ reduces to normalizing after multiplying by (c, d): the extra diagonal component is absorbed by normalization.

```
-- § Right cancellation at pair level: common successor adds a diagonal.
Pairℕ-mul-cancelRight : (p : Pairℕ) → (c d : ℕ) →

Pair-Level Associativity and ℤ Ring Closure

Associativity of $*_{\mathbb{Z}}$ cannot be proven by a single induction—the pair representation requires zero-annihilation base cases (seven combinations of a zero factor) and then eight nonzero cases, each expanding both association trees through canonical pair products and appealing to ℕ associativity. The lifting from pairs to signed integers uses the toPairℤ/fromPairℤ round-trip.

```
-- § Zero annihilation at pair level (right).
Pairℕ-mul-zero-right : (p : Pairℕ) → Pairℕ-mul p (mkPairℕ zero zero) ≡ (mkPairℕ zero zero)
Pairℕ-mul-zero-right (mkPairℕ a b) =
 pair-ext
  (trans
   (cong (λ t → t +ℕ (b *ℕ zero)) (*ℕ-zero-right a))
   (trans
    (cong (λ t → zero +ℕ t) (*ℕ-zero-right b))
    refl))
  (trans
   (cong (λ t → t +ℕ (b *ℕ zero)) (*ℕ-zero-right a))
```

```
  (trans
   (cong (λ t → zero +ℕ t) (*ℕ-zero-right b))
   refl))
 where
  pair-ext : {x y x' y' : ℕ} → x ≡ x' → y ≡ y' → (mkPairℕ x y) ≡ (mkPairℕ x' y')
  pair-ext refl refl = refl

-- § Zero annihilation at pair level (left).

```

Chapter 25

Integer Order Laws

Spectral operators send positive scalars to positive scalars and reflect the ordering: if the output is larger, the input was larger. Without these guarantees, eigenvalue comparisons would be meaningless and spectral gaps could not be bounded. Transport of $\leq_{\mathbb{Z}}$ along equality, antitone negation, positivity elimination, and monotone/cancellative multiplication are each forced by exhaustive sign-case analysis on the three constructors of $\mathbb{Z}$. The result is an ordered integral domain: multiplication by a positive factor preserves and reflects order, and strict inequality is preserved as well.

Transport and Negation

Transport of $\leq_{\mathbb{Z}}$ and $<_{\mathbb{Z}}$ along equalities is structurally trivial (refl leaves the witness unchanged), but must be stated explicitly so that later proofs can substitute equal values on either side of a comparison. Negation reverses order: $x \leq y$ implies $-y \leq -x$. The proof exhausts all nine sign-pair combinations.

```

Positivity Elimination

When a proof that $0 <_{\mathbb{Z}} z$ is in hand, the integer z must inhabit the +suc constructor—the zero and negative constructors are ruled out by the ordering. The elimination lemma and its immediate corollary ($0 <$ +suc n is trivially inhabited) provide the bridge from order-theoretic hypotheses to structural pattern matching.

```
-- § From 0 < z, force z into positive constructor form.
0<ℤ→pos : (z : ℤ) → 0ℤ <ℤ z → Σ ℕ (λ n → z ≡ +suc n)
0<ℤ→pos 0ℤ (p≤ , p≰) = ⊥-elim (p≰ p≤)
0<ℤ→pos (+suc n) _ = n , refl
0<ℤ→pos (-suc n) (() , _)

-- § 0 < +suc n is immediate.
0<ℤ-pos : (n : ℕ) → 0ℤ <ℤ (+suc n)
0<ℤ-pos n = tt , (λ p → p)
```

Multiplicative Monotonicity and Cancellation

Step 1: Product of positive constructors, positive multiplication, and negative-positive product. These three lemmas establish the concrete form of products involving positive (and negative) integers, and that multiplying a positive $\mathbb{N}^+$ stays positive.

```
opaque
 unfolding _*ℤ_
 -- § Product of positive constructors stays positive.

Chapter 26

Absolute Value Laws

The triangle inequality for the rational distance function $\mathrm{dist}_{\mathbb{Q}}$ rests on two pillars: subadditivity of the integer absolute value $|\cdot|_{\mathbb{Z}}$ and its compatibility with multiplication. Each law is forced by exhaustive sign-case analysis on the three constructors of $\mathbb{Z}$—no axiom, no choice, just pattern matching that the compiler verifies. The result is a forced norm: idempotent, nonnegative, subadditive, multiplicative, and injective at zero.

Basic Properties

The absolute value $|z|$ maps each integer to its nonneg representative. Nonnegativity of $|z|$, multiplicativity ($|z \cdot w| = |z| \cdot |w|$), the zero-test ($|z| = 0 \Rightarrow z = 0$), and compatibility with the order are the basic tools that all later distance and magnitude arguments will invoke.

absℤ-zero→zero (-suc n) ()
```

Magnitude and Subadditivity

The natural magnitude $\mathrm{mag}_{\mathbb{Z}}$ returns the underlying natural number regardless of sign. The embedding $\mathrm{from}_{\mathbb{N}\mathbb{Z}}$ sends it back to $\mathbb{Z}$. Magnitude is bounded by the input sum in the pair representation, and from this bound the subadditivity of $|\cdot|$ under $+_{\mathbb{Z}}$ follows.

```
-- § Natural magnitude.
magℤ : ℤ → ℕ
magℤ 0ℤ = zero
magℤ (+suc n) = suc n

≤-weaken-suc²ʳ : {a b : ℕ} → a ≤ b → a ≤ suc (suc b)
≤-weaken-suc²ʳ p = ≤-weaken-sucʳ (≤-weaken-sucʳ p)
```

Step 2: Subadditivity Core. The magnitude of $\mathrm{normalize}\mathbb{Z}$ is bounded by the input sum. From this, subadditivity of $\mathrm{mag}\mathbb{Z}$ and $\mathrm{abs}\mathbb{Z}$ under $+_{\mathbb{Z}}$ follows by bridging through the pair representation.

```
-- § mag of normalizeℤ is bounded by input sum.

   (fromℕℤ-+ℤ (magℤ x) (magℤ y)))
```

Multiplicative Compatibility

Absolute value must commute with multiplication by a positive right factor: $|z \cdot d| = |z| \cdot d$ for $d > 0$. The proof splits by the sign of z and applies the canonical product forms established in the preceding chapter. Full multiplicativity $|x \cdot y| = |x| \cdot |y|$ then follows by exhaustive sign-case analysis.

```
-- § abs commutes with multiplication by positive ℕ⁺.
absℤ-mul-pos-right : (z : ℤ) → (d : ℕ⁺) → absℤ (z *ℤ ⁺toℤ d) ≡ (absℤ z *ℤ ⁺toℤ d)

  (sym mulPosForm)

absℤ-mul-pos-right (-suc n) (mkℕ⁺ k) =
 let mulNegForm : (-suc n) *ℤ (+suc k) ≡ -suc (k +ℕ (n *ℕ suc k))
     mulNegForm = *ℤ-neg-pos-eq n k
     mulPosForm : (+suc n) *ℤ (+suc k) ≡ +suc (k +ℕ (n *ℕ suc k))
     mulPosForm = *ℤ-pos-pos-eq n k
 in
 trans
  (trans (cong absℤ mulNegForm) refl)
  (sym mulPosForm)
```

Step 2: Full Multiplicativity. The full multiplicativity proof $|x \cdot y| = |x| \cdot |y|$ follows by exhaustive sign-case analysis. Each case reduces to the positive product lemma *ℤ-pos-pos-eq combined with negation absorption.

```
-- § abs is fully multiplicative.

Chapter 27

Additive Monotonicity and Positive Natural Laws

The rational order infrastructure demands two ingredients that have not yet been established: general additive monotonicity for $\leq_{\mathbb{Z}}$, and the fact that the embedding of $\mathbb{N}^+$ into $\mathbb{Z}$ respects multiplication. Additive monotonicity is reduced, via the normalize/cross bridge, from $\mathbb{Z}$-order statements to $\mathbb{N}$-level cross-sum inequalities where the inductive structure does the work. The $\mathbb{N}^+$ laws then follow directly from their $\mathbb{N}$ counterparts. Together these close the last gaps: $+_{\mathbb{Z}}$ is monotone in both arguments, cancellative on the right, and the $\mathbb{N}^+$ multiplication homomorphism into $(\mathbb{Z}, *_{\mathbb{Z}})$ is exact.

Nonneg Monotonicity Bridge

The nonneg fragment of $\mathbb{Z}$ inherits the monotonicity of $\mathbb{N}$ addition through $\text{from}_{\mathbb{N}\mathbb{Z}}$. Left and right monotonicity, nonneg $+_{\mathbb{Z}}$ monotonicity, reflection of $\leq_{\mathbb{Z}}$ back to $\mathbb{N}$, and the nonnegativity elimination lemma are assembled here as the bridge between $\mathbb{N}$ arithmetic and $\mathbb{Z}$ order.

General Additive Monotonicity

Right, left, and both-slot monotonicity of $+_{\mathbb{Z}}$, together with right additive cancellation, extend the nonneg bridge to all of $\mathbb{Z}$. The proofs normalize both sides through the cross-sum bridge and apply $\mathbb{N}$-level monotonicity.

Integer arithmetic is rigid enough to support genuine spectral calculation. The K_4 neighbourhood structure, the Laplacian, simplex invariants, multiplication laws, and order laws are all forced into place. The graph is no longer just a survivor; it is an operator-bearing object.

But spectral data does not remain inside the integers. Ratios appear, and with them the need for quotient arithmetic, distance, and measurement. The next transition is therefore from integer combinatorics to rational evaluation.

Chapter 28

Rational Numbers and Measurement

Eigenvalue quotients from the K_4 spectral analysis—ratios of integers that are not themselves integers—demand a quotient field. $\mathbb{Q}$ is defined as the forced quotient $\mathbb{Z}/\mathbb{N}^+$: an integer numerator over a positive denominator, with equality given by the cross-multiplication setoid $a{\cdot}d = c{\cdot}b$. Distance is the absolute difference of two rationals, and measurement acts on Distinctions are classified as K_4-maps into the two-element carrier. The simplex evaluation $\alpha^{-1} = 137$ emerges as a forced combinatorial invariant of the graph, not a fitted parameter.

Rational Arithmetic

A rational number is an integer numerator over a positive denominator. Equality is the cross-multiplication setoid $a \cdot d = c \cdot b$, addition and multiplication lift through the common-denominator product, and distance is the absolute difference of the cross-products.

Simplex Evaluation: $\alpha^{-1} = 137$

The K_4 simplex invariants from the preceding chapter combine via the forced arithmetic to yield the integer 137. The canonicity of this particular combination—the proof that no other degree-≤ 3 expression in the invariant basis reaches 137—is established in §51. Agda requires the computation first and the classification later, because the classification depends on the full invariant ledger assembled across the intervening chapters.

Chapter 29

Rational Setoid and Order Laws

Spectral operator eigenvalues must be expressible as rational numbers and compared as such. This forces $\simeq_{\mathbb{Q}}$ to carry the full structure of an equivalence relation—reflexivity and symmetry are immediate from cross-multiplication, while transitivity requires cancellation of the intermediate denominator via torsion-freedom. The preorder $\leq_{\mathbb{Q}}$ then inherits its laws from multiplicative monotonicity of $\leq_{\mathbb{Z}}$. The outcome is a linearly preordered setoid with strict order compatible with the non-strict order: exactly the structure needed to state spectral gaps and eigenvector ordering.

Setoid Laws

Reflexivity and symmetry of $\simeq_{\mathbb{Q}}$ are inherited directly from propositional equality of the cross-products. Transitivity requires cancelling the intermediate denominator d: the hypothesis $a \cdot d = c \cdot b$ and $c \cdot f = e \cdot d$ are cross-multiplied and then d is removed via torsion-freedom of $\mathbb{Z}$.

Preorder Laws

Reflexivity of $\leq_{\mathbb{Q}}$ reduces to $\leq_{\mathbb{Z}}$-reflexivity of the common cross-product. Transitivity cross-multiplies both inequalities by the missing denominator, applies $\leq_{\mathbb{Z}}$-transitivity, and cancels the common factor via multiplicative monotonicity. The strict/non-strict compositions $\leq \circ <$ and $< \circ \leq$ are then derived from transitivity and irreflexivity.

Chapter 30

Laplacian as Finite-Index Operator

The Laplacian, defined on EndoCase-indexed functions in the preceding chapter, must now be re-expressed as a matrix operator on the canonical four-element index Fin 4. The bijection vertexAt/vertexIndex forces the Vec4-level operator to coincide with its EndoCase counterpart, and the diagonal/off-diagonal split is fixed by Fin4-decidable equality. Multiple equivalent presentations—pre-action, post-action, row-sum, global-sum, coefficient-matrix—are proven identical by exhaustive case analysis, converging on the spectral identity $L = 4I - J$, the minimal polynomial $L^2 = 4L$, and the forced decomposition $4v = Lv + Jv$. Every coefficient is dictated by the graph; no matrix entry is chosen.

Vec4 Infrastructure

A $\text{Vec4}_{\mathbb{Z}}$ is an integer-valued function on four canonical indices. The coefficient type $\text{Coeff}_{\mathbb{Z}}$ is closed: exactly four actions (zero, identity, negation, triple) survive, corresponding to the four places a Laplacian matrix entry can land. Coefficient and action matrices lift these pointwise.

```
-- § Vec4ℤ: integer-valued functions on the four canonical indices.

Mat4Coeffℤ = Fin4 → Fin4 → Coeffℤ

liftCoeffMatℤ : Mat4Coeffℤ → (Fin4 → Fin4 → Actℤ)
liftCoeffMatℤ m i j = coeffAct (m i j)

Mat4Actℤ : Set
Mat4Actℤ = Fin4 → Fin4 → Actℤ
```

Off-Diagonal Enumeration

For each index $i \in$ Fin4, the three neighbours are enumerated by others i. Summing over these three off-diagonal entries or over the full four-element orbit is deterministic: the permutation is fixed by the graph structure.

```
-- § others i k: the k-th index distinct from i (exhaustive by Fin3).

-- § Sum over the three off-diagonal indices.
sumOthersℤ : Vec4ℤ → Fin4 → ℤ
sumOthersℤ v i = sumFin3ℤ (λ k → v (others i k))
```

Laplacian on Vec4

The Laplacian acts as $Lv_i = 3v_i - \Sigma_{j \neq i} v_j$. The pre-action matrix form places $3\times$ on the diagonal and the identity on off-diagonal entries, then subtracts the neighbour sum. Conversion between the EndoCase and Fin4 representations is mediated by the canonical bijection.

```
-- § Laplacian: 3·v_i minus neighbor sum.

vecFromEndo f i = f (vertexAt i)

endoFromVec : Vec4ℤ → (EndoCase → ℤ)
endoFromVec v x = v (vertexIndex x)
```

Compatibility Laws

Law 14E.0 verifies that the EndoCase Laplacian factors through Fin4 indexing: the round-trip through vertexAt/vertexIndex is the identity. Law 14E.1 confirms that the pre-action matrix agrees with the direct Laplacian on all four indices.

```
-- § Law 14E.0: EndoCase Laplacian factors through Fin4 indexing.

law14E-1-matrix-agrees v g2 = refl
law14E-1-matrix-agrees v g3 = refl
```

Post-Action and Row-Sum Presentations

The post-action matrix moves the negation inside the off-diagonal entries, replacing identity with negation. Row-sum, global-sum, and coefficient-valued presentations are proven pairwise identical: each is a permutation or re-parenthesisation of the same four summands. Laws 14E.2–14E.9 confirm that all six matrix forms collapse to a single Laplacian operator.

Eigenvector Classification

Sum-zero vectors are 4-eigenvectors: when $\Sigma v = 0$, the $-\Sigma v$ term vanishes and $Lv = 4v$. Constant vectors are 0-eigenvectors: the $4v_i - 4v_i = 0$ cancellation is immediate. The J operator maps every vector to the constant vector at Σv, so $J \circ J = 4J$ and J as a coefficient matrix is the all-ones matrix.

```
-- § Law 14E.11: sum-zero vectors are 4-eigenvectors.

```

J Operator Properties

J is constant across indices, its sum is $4\Sigma v$, and J scales constants by 4. $J \circ J = 4J$ and the sum-zero criterion $\Sigma v = 0$ is equivalent to membership in the 4-eigenspace of L. These identities are assembled here as the spectral raw material for the decomposition $4v = Lv + Jv$.

Operator Identity and Kernel

Law 14E.21 establishes $L = 4I - J$ pointwise. The kernel condition $Lv_i = 0$ is then equivalent to $4v_i = Jv_i$, which forces every component to equal $\frac{1}{4}\Sigma v$—the defining property of constant vectors. Laws 14E.23–14E.27 package this equivalence in both directions.

Image of the Laplacian

Adding a constant c to every component shifts the global sum by $4c$. The core identity $\Sigma(Lv) = 0$ then follows from $L = 4I - J$ and the fact that $\Sigma(4v) = 4\Sigma v = \Sigma(Jv)$.

Minimal Polynomial and Operator Algebra

$L^2 = 4L$ is the minimal polynomial $x(x-4) = 0$: applying L twice to any vector reduces to four times the single application, because the image of L is sum-zero and therefore lies in the 4-eigenspace. $J \circ L = 0$ and $L + J = 4I$ close the operator algebra of K_4.

Chapter 31

Measurement Symmetries

Every measurement act $m : S\ d \to S$ Two defines a two-valued observable. Two symmetries act on such measurements without introducing new structure: swapping the output (post-composing with swapTwo) and swapping the input (pre-composing with the forced dual automorphism Distinction-dual). Each symmetry acts on the K_4Map classification by a forced permutation, and that permutation is determined by evaluation at the two constructors.

Output and Input Swap

The output swap post-composes with swapTwo, exchanging the two possible measurement outcomes. The input swap pre-composes with Distinction-dual, exchanging the two halves of the domain.

```
-- § output swap: post-compose with swapTwo
swapOut : {d : Distinction} → Measurement d → Measurement d
swapOut m x = swapTwo (m x)

-- § input swap: pre-compose with the forced dual
swapIn : (d : Distinction) → Measurement d → Measurement d
swapIn d m x = m (Distinction-dual d x)

-- § swapOut respects pointwise equality
swapOut-cong :
 {d : Distinction} {m n : Measurement d} →
 _≐_ {A = S d} {B = S Two-distinction} m n →
 _≐_ {A = S d} {B = S Two-distinction} (swapOut {d = d} m) (swapOut {d = d} n)
swapOut-cong p x = cong swapTwo (p x)

-- § swapIn respects pointwise equality
swapIn-cong :
 (d : Distinction) {m n : Measurement d} →
 _≐_ {A = S d} {B = S Two-distinction} m n →
 _≐_ {A = S d} {B = S Two-distinction} (swapIn d m) (swapIn d n)
swapIn-cong d p x = p (Distinction-dual d x)
```

Induced Permutations on EndoCase

The four-element classification EndoCase transforms under each symmetry by a forced permutation. Output swap exchanges constant-left with constant-right and identity with dual. Input swap fixes the constants and exchanges identity with dual.

```
-- § output swap acts on EndoCase
permOut : EndoCase → EndoCase
permOut case-constL = case-constR
permOut case-constR = case-constL
permOut case-id     = case-dual
permOut case-dual = case-id

-- § input swap acts on EndoCase
permIn : EndoCase → EndoCase
permIn case-constL = case-constL
permIn case-constR = case-constR
permIn case-id     = case-dual
permIn case-dual = case-id
```

Interpretation Compatibility

Each symmetry, when applied to the interpreted measurement case, yields the interpreted measurement of the permuted case. The identity and dual cases require the K_4Map module proofs for the two constructors.

```
-- § swapOut on interpreted cases equals interpretation of permOut
swapOut-interpret :
 (d : Distinction) →
 (c : EndoCase) →
 _≟̊_ {A = S d} {B = S Two-distinction}
  (swapOut {d = d} (K₄Map.interpret d Two-distinction c))
  (K₄Map.interpret d Two-distinction (permOut c))
swapOut-interpret d case-constL x = refl
swapOut-interpret d case-constR x = refl
swapOut-interpret d case-id x with cover d x
... | inj₁ _ = refl
... | inj₂ _ = refl
swapOut-interpret d case-dual x with cover d x
... | inj₁ _ = refl
... | inj₂ _ = refl
```

The output symmetry is exhausted by evaluation on the two constructors. Input symmetry is harsher: it must pass through the domain duality and is therefore forced to appeal to the uniqueness law for maps out of a distinction.

```
-- § swapIn on interpreted cases equals interpretation of permIn
swapIn-interpret :
 (d : Distinction) →
 (c : EndoCase) →
 _≟̊_ {A = S d} {B = S Two-distinction}
  (swapIn d (K₄Map.interpret d Two-distinction c))
```

```

Classification Laws

The uniqueness of the K_4Map classifier forces classification to commute with both symmetries. Each law reduces to showing that the permuted interpretation is pointwise equal to the symmetry-acted measurement, then invoking classify-unique.

Law 15C.0: Classification Respects Outcome Swap

The classifier is unique, so composing swapOut-interpret with the classification soundness witness yields pointwise agreement—swapping outcomes acts as permOut on the classification.

```
-- § classify commutes with output swap

  witness =
   ≐-trans
    (≐-sym (swapIn-interpret d (classify m)))
    (swapIn-cong d (classify-sound m))
```

Chapter 32

Rational Addition and Multiplication Laws

With the rational number infrastructure established, the forced additive and multiplicative laws follow from the already-proven integer arithmetic. Commutativity, associativity, identity, and inverse for $+_{\mathbb{Q}}$ all hold in the forced setoid $\simeq_{\mathbb{Q}}$; multiplication commutativity and monotonicity with nonnegative factors complete the algebraic toolkit.

Binary Congruence Helper

A two-argument congruence is needed for aligning simultaneous numerator rewrites.

```
-- § two-argument congruence
cong₂ : {A B C : Set} → (f : A → B → C) → {x x' : A} → {y y' : B} → x ≡ x' → y ≡ y' → f x y ≡ f x' y'
cong₂ f refl refl = refl
```

Commutativity of $+_{\mathbb{Q}}$

Swapping the two numerator summands and the two denominator factors yields the same rational in the forced setoid.

```
-- § rational addition commutes in ≃ℚ
+ℚ-comm : (p q : ℚ) → p +ℚ q ≃ℚ q +ℚ p
+ℚ-comm (a / b) (c / d) =
 let
  numComm : ((a *ℤ ⁺toℤ d) +ℤ (c *ℤ ⁺toℤ b)) ≡ ((c *ℤ ⁺toℤ b) +ℤ (a *ℤ ⁺toℤ d))
  numComm = +ℤ-comm (a *ℤ ⁺toℤ d) (c *ℤ ⁺toℤ b)

  denComm : (d *⁺ b) ≡ (b *⁺ d)
  denComm = *⁺-comm d b

  denCommℤ : ⁺toℤ (d *⁺ b) ≡ ⁺toℤ (b *⁺ d)
  denCommℤ = cong ⁺toℤ denComm

  lhsEq : (((a *ℤ ⁺toℤ d) +ℤ (c *ℤ ⁺toℤ b)) *ℤ ⁺toℤ (d *⁺ b))
          ≡

in
  lhsEq
```

Congruence of $+_{\mathbb{Q}}$

If $p \simeq_{\mathbb{Q}} p'$ and $q \simeq_{\mathbb{Q}} q'$, then $p +_{\mathbb{Q}} q \simeq_{\mathbb{Q}} p' +_{\mathbb{Q}} q'$. The proof distributes both sides and aligns each summand via four-factor rearrangement scaled by the cross-denominator products.

Chapter 33

Coupled K_4 Laplacian

The two forced coupling survivors—empty coupling (block-diagonal) and full coupling (K_8)—each generate a Laplacian operator on Vec8ℤ. This chapter derives the complete spectral theory of both operators, culminating in packaged spectral witnesses indexed by CouplingSurvivor.

Vec8 Infrastructure

A vector on $\mathrm{Fin}_4 \times \mathrm{Copy}_2$ decomposes as a pair of Vec4ℤ blocks. Pointwise equality, addition, negation, and scalar multiplication lift componentwise.

```
-- § 8-vectors as paired 4-vectors
Vec8ℤ : Set
Vec8ℤ = Vec4ℤ × Vec4ℤ

-- § left/right block projections
left4 : Vec8ℤ → Vec4ℤ
left4 = fst

right4 : Vec8ℤ → Vec4ℤ
right4 = snd

-- § pointwise equality on Vec8ℤ
Vec8Eq : Vec8ℤ → Vec8ℤ → Set
Vec8Eq u v = Vec4Eq (left4 u) (left4 v) × Vec4Eq (right4 u) (right4 v)

-- § pointwise addition on Vec8ℤ
+Vec8ℤ : Vec8ℤ → Vec8ℤ → Vec8ℤ
+Vec8ℤ u v = ((left4 u) +Vec4ℤ (left4 v)) , ((right4 u) +Vec4ℤ (right4 v))

-- § pointwise negation on Vec8ℤ
negVec8ℤ : Vec8ℤ → Vec8ℤ
negVec8ℤ v = (λ i → negℤ (left4 v i)) , (λ i → negℤ (right4 v i))

-- § pointwise four-times on Vec8ℤ
fourVec8ℤ : Vec8ℤ → Vec8ℤ
fourVec8ℤ v = (λ i → fourTimesℤ (left4 v i)) , (λ i → fourTimesℤ (right4 v i))

-- § global sum of all 8 entries
sum8ℤ : Vec8ℤ → ℤ
sum8ℤ v = sumFin4ℤ (left4 v) +ℤ sumFin4ℤ (right4 v)
```

```
-- § all-ones operator: constant with value sum8ℤ v
J8Vec8ℤ : Vec8ℤ → Vec8ℤ
J8Vec8ℤ v = constVec4ℤ (sum8ℤ v) , constVec4ℤ (sum8ℤ v)

-- § scalar ×8 on ℤ and on Vec4ℤ
eightTimesℤ : ℤ → ℤ
eightTimesℤ x = fourTimesℤ x +ℤ fourTimesℤ x

eightVec4ℤ : Vec4ℤ → Vec4ℤ
eightVec4ℤ v i = eightTimesℤ (v i)
```

K_8 Laplacian Definition

On the complete graph K_8, the Laplacian is $L_8\, v\, i = 8{\cdot}v_i - \Sigma_8\, v$. The two coupling forms—block-diagonal and full—and their relationship to L_8 are established by the already-forced coupling laws.

```
-- § K₈ Laplacian: 8·vᵢ − Σ₈ v
K8LaplacianVec8ℤ : Vec8ℤ → Vec8ℤ
K8LaplacianVec8ℤ v =

```

Coupling Survivors and Laplacian Dispatch

The data type CouplingSurvivor has exactly two constructors (Law 14G.6), and each selects the corresponding Laplacian form.

```
-- § coupling survivor type: empty or full
data CouplingSurvivor : Set where
 survivor-empty : CouplingSurvivor
 survivor-full : CouplingSurvivor

-- § forced coupling for each survivor
survivorCoupling : CouplingSurvivor → Coupling
survivorCoupling survivor-empty = CrossEmpty
survivorCoupling survivor-full = CrossFull

-- § Laplacian dispatched by survivor case
laplacianSurvivorVec8ℤ : CouplingSurvivor → Vec8ℤ → Vec8ℤ
```

```
laplacianSurvivorVec8ℤ survivor-empty = laplacianEmptyVec8ℤ
laplacianSurvivorVec8ℤ survivor-full = laplacianFullVec8ℤ

-- § constant and zero 8-vectors
constVec8ℤ : ℤ → Vec8ℤ
constVec8ℤ x = constVec4ℤ x , constVec4ℤ x

zeroVec8ℤ : Vec8ℤ
zeroVec8ℤ = constVec8ℤ 0ℤ

eightVec8ℤ-const : ℤ → Vec8ℤ
eightVec8ℤ-const x = constVec8ℤ (eightTimesℤ x)
```

Coupling Classification and Block Laws

Law 14G.0: Empty Coupling Is Block-Diagonal

With zero cross-coupling, the two K_4 blocks decouple completely—the Laplacian on the product is definitionally equal to the block-diagonal form, and the empty survivor acts independently on each 4-block.

```
-- § empty coupling = block-diagonal Laplacian
law14G-0-empty-block : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (laplacianEmptyVec8ℤ v)
law14G-0-empty-block v = (λ _ → refl) , (λ _ → refl)
```

Law 14G.1: Full Coupling Yields K_8 Laplacian

The full coupling Laplacian must equal L_8 pointwise. On each block, the three summands $(L_4\, v\, i + 4 \cdot v_i - \Sigma_{\text{other}})$ reassociate into $(8 \cdot v_i - \Sigma_8\, v)$ via Law 14E.10 and additive regrouping, confirming that the full survivor is exactly the complete-graph Laplacian.

Figure 33.1 records the entire situation in one line: two survivor cases, two operators, two spectral regimes. Nothing else survives dispatch.

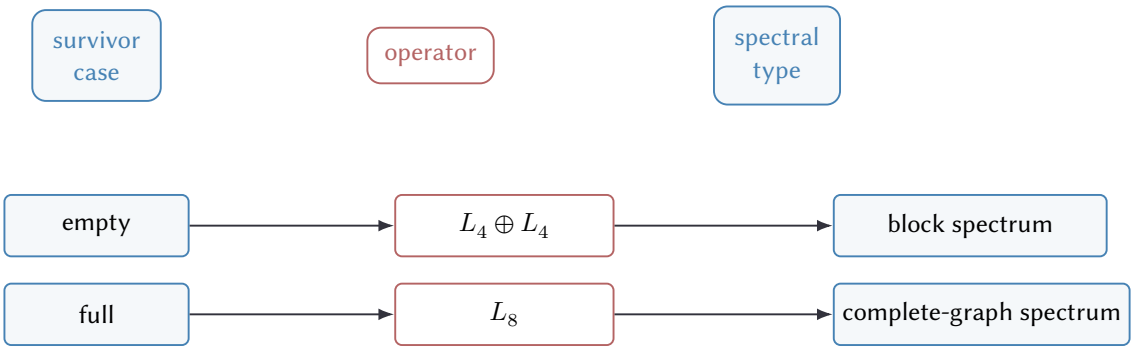

Figure 33.1: Coupling survivor dispatch. Empty and full are the only surviving cases, and each determines one operator and one spectral regime.

```
-- § full coupling = K8 Laplacian

```

Laws 14G.2–14G.5: Edge/Non-Edge Forcing and Coupling Form Constraints

Each edge and non-edge condition on the endo-permutation group forces the coupling to be exactly one of the two survivors.

```
-- § edge forces full coupling via 14F.0
law14G-2-edge-forces-full : Coupling
law14G-2-edge-forces-full = CrossFull

-- § non-edge forces empty coupling via 14F.1
law14G-3-nonedge-forces-empty : Coupling
law14G-3-nonedge-forces-empty = CrossEmpty

-- § edge → full survivor
law14G-4-edge-full : CouplingSurvivor
law14G-4-edge-full = survivor-full

-- § non-edge → empty survivor
law14G-5-nonedge-empty : CouplingSurvivor
law14G-5-nonedge-empty = survivor-empty
```

Law 14G.6: Exactly Two Forced Survivors

The coupling type has exactly two constructors: empty and full. No third alternative exists because any intermediate cross-coupling would break either block-diagonality or the complete-graph identity.

```
-- § survivor case split
law14G-6-survivor-cases : (k : CouplingSurvivor) → (k ≡ survivor-empty) ⊎ (k ≡ survivor-full)
law14G-6-survivor-cases survivor-empty = inj₁ refl
law14G-6-survivor-cases survivor-full = inj₂ refl
```

Laws 14G.7–14G.8: Survivor-to-Operator Identification

Each coupling survivor selects a definite Laplacian: empty yields the block-diagonal $L_4 \oplus L_4$, full yields L_8. The identification is exhaustive—every CouplingSurvivor constructor dispatches to exactly one operator.

```
-- § empty survivor = block-diagonal
law14G-7-survivor-empty-block : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (laplacianEmptyVec8ℤ v)
law14G-7-survivor-empty-block = law14G-0-empty-block

```

Global Sum Law and Operator Annihilation

Law 14G.12: $\Sigma_8(L_8\, v) = 0$

Summing $8 \cdot v_i - \Sigma_8\, v$ over all eight vertices produces $8 \cdot \Sigma_8\, v - 8 \cdot \Sigma_8\, v$, which collapses by $+\mathbb{Z}$-inv-right. The global sum of any K_8 Laplacian image is therefore zero, forcing $J_8(L_8\, v) = 0$ and eliminating all leftover drift terms.

```
-- § global sum of K8 Laplacian is 0
law14G-12-sumL8-0 : (v : Vec8ℤ) → sum8ℤ (K8LaplacianVec8ℤ v) ≡ 0ℤ
```

```
law14G-12-sumL8-0 v =

Law 14G.13: $J_8(L_8\, v) = 0$

Since J_8 broadcasts Σ_8 and Law 14G.12 forces that sum to zero, the image of L_8 lies entirely in the sum-zero subspace.

```
-- § J₈ (L₈ v) = 0
law14G-13-JL-zero : (v : Vec8ℤ) → Vec8Eq (J8Vec8ℤ (K8LaplacianVec8ℤ v)) zeroVec8ℤ
law14G-13-JL-zero v =
 let sum0 = law14G-12-sumL8-0 v in
 (λ _ → sum0) , (λ _ → sum0)
```

Law 14G.14: $L_8(J_8\, v) = 0$

$J_8\, v$ is constant with value $\Sigma_8\, v$; applying L_8 yields $8 \cdot \Sigma - \Sigma(J_8\, v)$, and by sum8-J8 both terms coincide. So L and J annihilate each other.

```
-- § L₈ (J₈ v) = 0

 ( λ _ →
     trans
      (cong (λ t → eightTimesℤ s +ℤ negℤ t) sj)
      (+ℤ-inv-right (eightTimesℤ s))
 )
```

Law 14G.15: $L_8 \circ L_8 = 8 \cdot L_8$

Each coordinate of $L_8(L_8\, v)$ equals $8 \cdot (L_8\, v)_i - \Sigma_8(L_8\, v)$, and Law 14G.12 forces the sum term to vanish. The minimal polynomial of L_8 therefore has degree at most 2.

```
-- § L₈² = 8·L₈
law14G-15-LL-eightL : (v : Vec8ℤ) → Vec8Eq (K8LaplacianVec8ℤ (K8LaplacianVec8ℤ v)) (eightVec8ℤ (K8LaplacianVec8ℤ v))

 ) ,
 ( λ i →
     trans
      (cong (λ t → eightTimesℤ (right4 (K8LaplacianVec8ℤ v) i) +ℤ negℤ t) sum0)
      (+ℤ-zero-right (eightTimesℤ (right4 (K8LaplacianVec8ℤ v) i)))
 )
```

Spectral Classification on K_8

All remaining freedom in the spectrum of L_8 collapses here. The forcing chain pins the image of L_8 to the 8-eigenspace and the kernel to the constant subspace.

Law 14G.16: Sum-Zero Forces 8-Eigenvector

Each coordinate of $L_8\, v$ is $8 \cdot v_i - \Sigma_8\, v$. Imposing $\Sigma_8\, v = 0$ eliminates the subtraction term everywhere, forcing every sum-zero vector into the 8-eigenspace.

```
– § Σ₈ v = 0 => L₈ v = 8·v
law14G-16-sum0-eigen8 : (v : Vec8ℤ) → sum8ℤ v ≡ 0ℤ → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v)
law14G-16-sum0-eigen8 v sum0 =
 ( λ i →
     trans
      (cong (λ s → eightTimesℤ (left4 v i) +ℤ negℤ s) sum0)
      (+ℤ-zero-right (eightTimesℤ (left4 v i)))
 ) ,
 ( λ i →
     trans
      (cong (λ s → eightTimesℤ (right4 v i) +ℤ negℤ s) sum0)
      (+ℤ-zero-right (eightTimesℤ (right4 v i)))
 )
```

Law 14G.17: Pointwise 8-Eigen Forces Sum-Zero

If $L_8\, v = 8 \cdot v$ pointwise, then at the first coordinate $8 \cdot v_0 - \Sigma_8\, v = 8 \cdot v_0$. Cancelling the common term leaves $-\Sigma_8\, v = 0$, so the 8-eigenspace is exactly the sum-zero subspace.

```
– § L₈ v = 8·v => Σ₈ v = 0
law14G-17-eigen8→sum0 : (v : Vec8ℤ) → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ
law14G-17-eigen8→sum0 v eigen8 =
 let a = eightTimesℤ (left4 v g0) in
 let s = sum8ℤ v in
 let eq₀ : a +ℤ negℤ s ≡ a
     eq₀ = fst eigen8 g0
 in
 negℤ-zero→zero s (+ℤ-cancel-left a (negℤ s) eq₀)
```

Law 14G.18: Biconditional Sum-Zero ⇔ 8-Eigen

Law 14G.16 and Law 14G.17 force both directions of the equivalence: no intermediate spectral case survives between sum-zero and 8-eigen. The two predicates are definitionally packaged as one biconditional.

```
-- § sum0 ↔ eigen8 (both directions)
law14G-18-sum0→eigen8 : (v : Vec8ℤ) → sum8ℤ v ≡ 0ℤ → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v)
law14G-18-sum0→eigen8 = law14G-16-sum0-eigen8

law14G-18-eigen8→sum0 : (v : Vec8ℤ) → Vec8Eq (K8LaplacianVec8ℤ v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ
law14G-18-eigen8→sum0 = law14G-17-eigen8→sum0
```

Law 14G.19: Constants Are Forced 0-Eigenvectors

A constant vector with value x has total sum $8{\cdot}x$, and each coordinate of L_8 becomes $8{\cdot}x - 8{\cdot}x = 0$. The constant subspace therefore survives exactly as the 0-eigenspace.

```
-- § constant vectors lie in kernel of L₈
law14G-19-const-eigen0 : (x : ℤ) → Vec8Eq (K8LaplacianVec8ℤ (constVec8ℤ x)) zeroVec8ℤ
law14G-19-const-eigen0 x =
 let sc : sum8ℤ (constVec8ℤ x) ≡ eightTimesℤ x
     sc =

      (cong (λ s → eightTimesℤ x +ℤ negℤ s) sc)
      (+ℤ-inv-right (eightTimesℤ x))
 ) ,
 ( λ _ →
     trans
      (cong (λ s → eightTimesℤ x +ℤ negℤ s) sc)
      (+ℤ-inv-right (eightTimesℤ x))
 )
```

Law 14G.20: Kernel Condition $L_8\, v = 0 \Leftrightarrow 8 \cdot v = J_8\, v$

The kernel equation at each coordinate reads $8 \cdot v_i - \Sigma_8\, v = 0$. Moving the sum term across the equality forces $8 \cdot v_i = \Sigma_8\, v$, which is precisely the broadcast equation $8 \cdot v = J_8\, v$. Kernel membership is thus classified without residue.

```

Laws 14G.21–14G.22: Image Characterization

The image of L_8 is obtained by applying L_8 once, so Law 14G.15 applies immediately and pins every image vector to the 8-eigenspace. Law 14G.16 then confirms that every sum-zero vector supplies an explicit preimage after 8-scaling—the image and the 8-eigenspace coincide.

```
-- § image vectors are 8-eigenvectors
law14G-21-image⊆eigen8 : (v : Vec8ℤ) → Vec8Eq (K8LaplacianVec8ℤ (K8LaplacianVec8ℤ v)) (eightVec8ℤ (K8LaplacianVec8ℤ v))
law14G-21-image⊆eigen8 = law14G-15-LL-eightL

-- § sum-zero vectors become image vectors after 8-scaling

```

Full Survivor: Forced Spectral Consequences

The already-forced K_8 spectral laws transfer directly to the full survivor. Law 14G.8 eliminates any distinction between the full survivor Laplacian and L_8, so every remaining consequence is forced by transport.

Law 14G.23: $\Sigma_8(L_{\text{full}}\, v) = 0$

The full survivor coincides pointwise with L_8 by Law 14G.8, so the sum computation reduces to Law 14G.12 directly—the full-survivor image is forced into the sum-zero subspace.

```
-- § global sum of the full-survivor Laplacian is 0
law14G-23-sumL-survivor-full-0 : (v : Vec8ℤ) → sum8ℤ (laplacianSurvivorVec8ℤ survivor-full v) ≡ 0ℤ
law14G-23-sumL-survivor-full-0 v =
 trans
  (sum8-cong (laplacianSurvivorVec8ℤ survivor-full v) (K8LaplacianVec8ℤ v) (law14G-8-survivor-full-K8 v))
  (law14G-12-sumL8-0 v)
```

Law 14G.24: $J_8(L_{\text{full}}\, v) = 0$

Because J_8 broadcasts the global sum of its input and Law 14G.23 forces that sum to vanish, J_8 annihilates every vector in the full-survivor image.

```
-- § J₈ annihilates full-survivor image
law14G-24-JL-survivor-full-zero : (v : Vec8ℤ) → Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)) zeroVec8ℤ
law14G-24-JL-survivor-full-zero v =
 let sum0 = law14G-23-sumL-survivor-full-0 v in
 (λ _ → sum0) , (λ _ → sum0)
```

Laws 14G.25–14G.26: Sum-Zero ⇔ 8-Eigen for Full Survivor

Under Law 14G.8 the full survivor is L_8, so Law 14G.16 and Law 14G.17 transfer across that identification without adding new cases. Sum-zero and 8-eigen remain the unique surviving conditions.

```
-- § sum-zero → 8-eigenvector for full survivor
law14G-25-survivor-full-sum0→eigen8 : (v : Vec8ℤ) → sum8ℤ v ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v)

 Vec8Eq-trans
  (law14G-8-survivor-full-K8 v)
  (law14G-16-sum0-eigen8 v sum0)

-- § 8-eigenvector → sum-zero for full survivor
law14G-26-survivor-full-eigen8→sum0 : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ
law14G-26-survivor-full-eigen8→sum0 v eigen8 =
 law14G-17-eigen8→sum0 v
  (Vec8Eq-trans
   (Vec8Eq-sym (law14G-8-survivor-full-K8 v))
   eigen8)
```

Empty Survivor: Forced Block Spectral Consequences

The empty survivor reduces to two independent K_4 blocks. Block diagonality eliminates every cross-term, so the surviving spectral laws are forced blockwise from the earlier K_4 development.

Law 14G.27: $\Sigma_8(L_{\text{empty}}\, v) = 0$

Block diagonality splits the total sum of the empty survivor into the left and right K_4 Laplacian sums. Law 14E.28 forces each block sum to vanish independently, so the empty-survivor image lies in the global sum-zero subspace.

```
-- § global sum of empty-survivor Laplacian is 0
law14G-27-sumL-survivor-empty-0 : (v : Vec8ℤ) → sum8ℤ (laplacianSurvivorVec8ℤ survivor-empty v) ≡ 0ℤ
law14G-27-sumL-survivor-empty-0 v =
 trans
  (cong (λ t → t +ℤ sumFin4ℤ (laplacianVec4ℤ (right4 v))) (law14E-28-sumLaplacian0 (left4 v)))
  (trans
   (cong (λ t → 0ℤ +ℤ t) (law14E-28-sumLaplacian0 (right4 v)))
   (+ℤ-zero-left 0ℤ))
```

Law 14G.28: $J_8(L_{\text{empty}}\, v) = 0$

Since J_8 depends only on the global sum of its input and Law 14G.27 eliminates that sum, the empty-survivor image is annihilated by J_8.

```
-- § J₈ annihilates empty-survivor image
law14G-28-JL-survivor-empty-zero : (v : Vec8ℤ) → Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)) zeroVec8ℤ
law14G-28-JL-survivor-empty-zero v =
 let sum0 = law14G-27-sumL-survivor-empty-0 v in
 (λ _ → sum0) , (λ _ → sum0)
```

Laws 14G.29–14G.30: Blockwise Sum-Zero ⇔ 4-Eigen for Empty Survivor

The empty survivor acts as two independent K_4 Laplacians. Law 14E.11 and Law 14E.19 classify each block separately, leaving no mixed alternative—blockwise sum-zero and pointwise 4-eigen are the unique surviving conditions.

```
-- § blockwise sum-zero → pointwise 4-eigenvector for empty survivor
law14G-29-survivor-empty-sum0→eigen4 : (v : Vec8ℤ) → sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ →
 Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v)
law14G-29-survivor-empty-sum0→eigen4 v sum0L sum0R =
 ( λ i → law14E-11-sum0-eigen4 (left4 v) i sum0L ) ,
 ( λ i → law14E-11-sum0-eigen4 (right4 v) i sum0R )

-- § pointwise 4-eigen → blockwise sum-zero for empty survivor
law14G-30-survivor-empty-eigen4→sum0 : (v : Vec8ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v) →
 (sumFin4ℤ (left4 v) ≡ 0ℤ) × (sumFin4ℤ (right4 v) ≡ 0ℤ)
law14G-30-survivor-empty-eigen4→sum0 v eigen4 =
 law14E-19-eigen4→sum0 (left4 v) (fst eigen4) ,
 law14E-19-eigen4→sum0 (right4 v) (snd eigen4)
```

Law 14G.31: Split Constants Are 0-Eigenvectors of the Empty Survivor

On each block, a constant vector is already a forced 0-eigenvector of the K_4 Laplacian. Block diagonality prevents the two constants from interacting across blocks, so split constants survive exactly as kernel witnesses for the empty survivor.

```
-- § split constant vector
constVec8Splitℤ : ℤ → ℤ → Vec8ℤ
constVec8Splitℤ x y = constVec4ℤ x , constVec4ℤ y

-- § split constants lie in kernel of empty survivor
law14G-31-splitConst-eigen0-empty : (x y : ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (constVec8Splitℤ x y)) zeroVec8ℤ
law14G-31-splitConst-eigen0-empty x y =
 ( λ i → law14E-13-const-eigen0 x i ) ,
 ( λ i → law14E-13-const-eigen0 y i )
```

Law 14G.32: Empty Survivor Image is 4-Eigen

Applying the empty survivor twice applies each K_4 Laplacian twice on its own block. Law 14E.29 collapses each repeated block action to 4 times the first image, forcing every vector in the empty-survivor image into the 4-eigenspace.

```
-- § image of empty survivor ⊆ 4-eigenspace
law14G-32-imageEmpty⊆eigen4 : (v : Vec8ℤ) →
 Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (laplacianSurvivorVec8ℤ survivor-empty v))
  (fourVec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v))
law14G-32-imageEmpty⊆eigen4 v =
 ( λ i → law14E-29-LL-fourL (left4 v) i ) ,
 ( λ i → law14E-29-LL-fourL (right4 v) i )
```

Law 14G.33: Sum-Zero ⇒ Image Witness After 4-Scaling

Law 14G.29 already forces a blockwise sum-zero vector to satisfy the empty-survivor eigenvalue equation. Choosing the vector itself as preimage eliminates any search for an additional witness—every blockwise sum-zero vector has an explicit image witness after 4-scaling.

```
-- § blockwise sum-zero → 4·v is in the image
law14G-33-sum0→fourInImage-empty : (v : Vec8ℤ) → sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ →
 Σ Vec8ℤ (λ w → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty w) (fourVec8ℤ v))
law14G-33-sum0→fourInImage-empty v sum0L sum0R = v , law14G-29-survivor-empty-sum0→eigen4 v sum0L sum0R
```

Full Survivor Image Law

The image law for the full survivor is a direct transport consequence. No new spectral case appears here; Law 14G.15 is merely re-expressed through the survivor identification.

Law 14G.34: Full Survivor Image ⊆ 8-Eigenspace

The full survivor is identified with L_8 both before and after one further application, so the claim reduces to Law 14G.15 by transport on both sides. Scaling congruence carries the codomain back, forcing the full-survivor image into the 8-eigenspace.

```
– § full survivor image vectors are 8-eigenvectors
law14G-34-survivor-full-image⊆eigen8 : (v : Vec8ℤ) →
 Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
     (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v))
law14G-34-survivor-full-image⊆eigen8 v =

     step₂ : Vec8Eq (K8LaplacianVec8ℤ (K8LaplacianVec8ℤ v)) (eightVec8ℤ (K8LaplacianVec8ℤ v))
     step₂ = law14G-15-LL-eightL v
     step₃ : Vec8Eq (eightVec8ℤ (K8LaplacianVec8ℤ v)) (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v))
     step₃ = Vec8Eq-sym (eightVec8-cong (laplacianSurvivorVec8ℤ survivor-full v) (K8LaplacianVec8ℤ v) eqV)
 in
 Vec8Eq-trans step₁ (Vec8Eq-trans step₂ step₃)
```

Survivor Spectral Packages

Packaging the already-forced survivor consequences into reusable witnesses adds no new ontology—it only collects the eliminated cases into a single typed interface.

Law 14G.35: Full Survivor Spectral Package

Law 14G.23, Law 14G.24, Laws 14G.25–14G.26, and Law 14G.34 already force all full-survivor spectral data. Product formation collects those forced components without introducing any new branch, yielding a single composite spectral witness.

```
– § full survivor spectral package
law14G-35-survivor-full-spectral-package : (v : Vec8ℤ) →
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-full v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)) zeroVec8ℤ) ×
 ((sum8ℤ v ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v)) ×
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ)) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
```

```
  (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)))
law14G-35-survivor-full-spectral-package v =
 law14G-23-sumL-survivor-full-0 v ,
 (law14G-24-JL-survivor-full-zero v ,
  ((law14G-25-survivor-full-sum0→eigen8 v , law14G-26-survivor-full-eigen8→sum0 v) ,
   law14G-34-survivor-full-image⊆eigen8 v))
```

Law 14G.36: Empty Survivor Spectral Package

Law 14G.27 through Law 14G.32 already force the empty-survivor spectral data. The blockwise consequences and kernel witnesses are collected as one product—a single composite spectral witness for the empty survivor.

```
– § empty survivor spectral package
law14G-36-survivor-empty-spectral-package : (v : Vec8ℤ) →
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-empty v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)) zeroVec8ℤ) ×
 ((sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v)) ×
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v) → (sumFin4ℤ (left4 v) ≡ 0ℤ) × (sumFin4ℤ (right4 v) ≡ 0ℤ))) ×
 ((x y : ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (constVec8Splitℤ x y)) zeroVec8ℤ) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (laplacianSurvivorVec8ℤ survivor-empty v))
  (fourVec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)))
law14G-36-survivor-empty-spectral-package v =
 law14G-27-sumL-survivor-empty-0 v ,
 (law14G-28-JL-survivor-empty-zero v ,
  ((law14G-29-survivor-empty-sum0→eigen4 v , law14G-30-survivor-empty-eigen4→sum0 v) ,
   (law14G-31-splitConst-eigen0-empty ,
    law14G-32-imageEmpty⊆eigen4 v)))
```

Law 14G.37: Spectral Package by Forced Case Split

The survivor type has exactly two constructors by Law 14G.6. Exhaustive case split eliminates every index except survivor-empty and survivor-full, forcing a uniform survivor-indexed spectral package for every case.

```
– § type-level spectral package indexed by survivor
SurvivorSpectralPackage : CouplingSurvivor → Vec8ℤ → Set
SurvivorSpectralPackage survivor-full v =
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-full v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)) zeroVec8ℤ) ×
 ((sum8ℤ v ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v)) ×
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full v) (eightVec8ℤ v) → sum8ℤ v ≡ 0ℤ)) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-full (laplacianSurvivorVec8ℤ survivor-full v))
  (eightVec8ℤ (laplacianSurvivorVec8ℤ survivor-full v)))
SurvivorSpectralPackage survivor-empty v =
 (sum8ℤ (laplacianSurvivorVec8ℤ survivor-empty v) ≡ 0ℤ) ×
 (Vec8Eq (J8Vec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)) zeroVec8ℤ) ×
 ((sumFin4ℤ (left4 v) ≡ 0ℤ → sumFin4ℤ (right4 v) ≡ 0ℤ → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v)) ×
  (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty v) (fourVec8ℤ v) → (sumFin4ℤ (left4 v) ≡ 0ℤ) × (sumFin4ℤ (right4 v) ≡ 0ℤ))) ×
 ((x y : ℤ) → Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (constVec8Splitℤ x y)) zeroVec8ℤ) ×
 (Vec8Eq (laplacianSurvivorVec8ℤ survivor-empty (laplacianSurvivorVec8ℤ survivor-empty v))
  (fourVec8ℤ (laplacianSurvivorVec8ℤ survivor-empty v)))

– § forced case-split over survivor constructors
law14G-37-survivor-spectral-package-byCases : (k : CouplingSurvivor) (v : Vec8ℤ) → SurvivorSpectralPackage k v
```

```
law14G-37-survivor-spectral-package-byCases k v with law14G-6-survivor-cases k
... | inj₁ refl = law14G-36-survivor-empty-spectral-package v
... | inj₂ refl = law14G-35-survivor-full-spectral-package v
```

Spectral Package Projections

Each forced component of the survivor package is projected directly from the already-fixed product witness, without reopening the classification.

```
-- § project drift-zero from package
survivorPkg-sumL0 : {k : CouplingSurvivor} {v : Vec8ℤ} →
 SurvivorSpectralPackage k v → sum8ℤ (laplacianSurvivorVec8ℤ k v) ≡ 0ℤ
survivorPkg-sumL0 {survivor-full} pkg = fst pkg
survivorPkg-sumL0 {survivor-empty} pkg = fst pkg

-- § project JL=0 from package
survivorPkg-JL0 : {k : CouplingSurvivor} {v : Vec8ℤ} →

Chapter 34

Triple K_4 Laplacian

The two-copy coupled Laplacian of the previous chapter forced a binary classification: full join or disjoint union, with eigenvalue 8 governing the spectral theory. Three copies force the same elimination again, now under the copy symmetry of S_3 and the endomorphism symmetries on each K_4 factor. These constraints eliminate every intermediate coupling, force the same binary survivors, and then force the 12-vertex operator algebra and its spectral packages.

Copy_3 Infrastructure

Three copies, decidable equality for each pair, and the full symmetric group S_3 are forced as the minimal copy infrastructure. Representation freedom collapses once the copy type, its equality test, and the six explicit bijections that exhaust the copy symmetries are fixed.

```
-- § three indistinguishable copies
data Copy3 : Set where
  C₀ : Copy3
  C₁ : Copy3
  C₂ : Copy3

-- § copy-inequality predicate
Copy3≠ : (i j : Copy3) → Set
Copy3≠ i j = i ≡ j → ⊥

C₀≠C₁ : Copy3≠ C₀ C₁
C₀≠C₁ ()

C₀≠C₂ : Copy3≠ C₀ C₂
C₀≠C₂ ()

C₁≠C₂ : Copy3≠ C₁ C₂
C₁≠C₂ ()

-- § decidable equality on Copy3 (9 cases)
Copy3-decEq : (i j : Copy3) → (i ≡ j) ⊎ (Copy3≠ i j)
Copy3-decEq C₀ C₀ = inj₁ refl
Copy3-decEq C₁ C₁ = inj₁ refl
Copy3-decEq C₂ C₂ = inj₁ refl
Copy3-decEq C₀ C₁ = inj₂ C₀≠C₁
Copy3-decEq C₁ C₀ = inj₂ (λ e → C₀≠C₁ (sym e))
```

```
Copy3-decEq C₀ C₂ = inj₂ C₀≠C₂
Copy3-decEq C₂ C₀ = inj₂ (λ e → C₀≠C₂ (sym e))

Coupling Classification

The binary coupling dichotomy for three copies is forced here. One cross-edge witness forces the complete join, one cross-non-edge witness forces total separation, and no intermediate coupling survives the copy and endomorphism symmetries.

```
-- § Law 14H.0: one cross-edge forces complete join across all copies
law14H-0-edge-forces-all-cross3 : (C : Coupling3) → EndoInv3 C → CopyInv3 C →

sum12-J12 v = refl
```

K_{12} Operator Algebra

Once L_{12} is fixed as $12I - J_{12}$, the operator algebra is forced. The identities $J^2 = 12J$, $L + J = 12I$, and the remaining operator equalities follow without further branching.

```
-- § Law 14H.5: J₁₂² = 12·J₁₂
law14H-5-JJ-twelveJ : (v : Vec12ℤ) → Vec12Eq (J12Vec12ℤ (J12Vec12ℤ v)) (twelveVec12ℤ (J12Vec12ℤ v))
law14H-5-JJ-twelveJ v =
 (λ _ → sum12-J12 v) ,
 ((λ _ → sum12-J12 v) ,
  (λ _ → sum12-J12 v))
```

Step 2: Laplacian Operator Identities. With $J^2 = 12J$ established, the remaining operator identities require unfolding the opaque Laplacian definition. The decomposition $12v = Lv + Jv$, scalar distributivity of $12\times$, and the sum–Laplacian commutation all follow inside a single opaque scope.

```

K_{12} Operator Annihilation

The annihilation relations between J_{12} and L_{12} are forced here. Once Law 14H.8 eliminates the total sum of $L_{12}v$, both mixed composites collapse to zero and the double Laplacian collapses to $12 \cdot L_{12}$.

The spectral theory of the coupled and triple K_4 Laplacians is complete. Every iterated operator word collapses to one of four normal forms—identity, pure L-power, pure J-power, or zero—and the eigenvalue spectrum is exhausted by $\{0, 4, 12\}$. The survivor structure of K_4 is fully extracted into operator algebra, and no spectral degree of freedom remains.

The spectral data is exact, but the arithmetic on which it rests—$\mathbb{Z}$ and $\mathbb{Q}$—is not yet equipped with the order and distance infrastructure that convergence arguments demand. The next chapters forge that infrastructure: additive order monotonicity, rational multiplication, ε-splitting, and distance laws. These are not new structure; they are the forced algebraic consequences of the integer and rational definitions already fixed. Once they are in place, the spectral data will have a metric home, and the passage to the reals will become inevitable.

A physics breadcrumb. The reader who has tracked the numbers should notice: the graph has 4 vertices and an eigenvalue ratio 3:1 (three copies of eigenvalue 4, one copy of eigenvalue 0). These ratios will reappear when the derived constants are compared to independently measured quantities. The elimination is not yet complete, but the spectral fingerprint that will underlie the fine-structure computation is already fully determined.

Chapter 35

Additive Order Laws for $\leq_{\mathbb{Q}}$

Cauchy convergence arguments require combining two distance bounds into one: if $|x_m - x_n| < \varepsilon/2$ and $|x_n - x_k| < \varepsilon/2$, then $|x_m - x_k| < \varepsilon$. This chapter establishes the additive monotonicity and sum-doubling laws for the rational order. Nonnegative rationals must remain closed under addition, and each order comparison must be stable under adding the same quantity on either side. These constraints force the additive order toolkit used later in the Cauchy arguments.

Nonnegativity Extraction and Closure

Nonnegativity must survive passage from rationals to numerators and back through addition. The reduction always collapses to integer nonnegativity after clearing denominators.

Sum-Doubling Bounds

If $0 \leq x, y, z$ with $x \leq z$ and $y \leq z$, then $x + y \leq z + z$. The integer version lifts through the natural-number representation, and the rational version is forced by the same bound after scaling to a common denominator.

```

Nonneg-Right Addition and Monotonicity

Adding a nonnegative term on the right preserves the order; this extends to full left and right monotonicity of rational addition. Directional ambiguity is eliminated by forcing right-monotonicity first and then transporting left-monotonicity through commutativity.

```

Chapter 36

K_{12} Iteration and Word Algebra

Every iterated application of the K_{12} Laplacian or global-sum operator collapses to a scaled first application. Combined with the annihilation laws $JL = LJ = 0$, this forces every word in the free monoid on $\{L_{12}, J_{12}\}$ to reduce to one of exactly four normal forms: identity, pure L-power, pure J-power, or zero. These relations force all iterated behaviour from the quadratic identities of the Triple K_4 and K_{12} spectral chapter. Induction then eliminates every mixed word except the four surviving normal forms and fixes the complete word algebra.

$\mathbf{Vec}_{12}$ Transport

Reflexivity, symmetry, transitivity for pointwise equality, plus congruence of the sum, scaling, and Laplacian operators. All transport ambiguity is eliminated by fixing how Vec_{12} equalities pass through the three basic operators used in the iteration laws.

```

Iterated Operator Collapse

Laws 14K.0–14K.2: every iterate of L_{12} or J_{12} beyond the first is a 12-scaled copy of its predecessor. The quadratic identities from the previous chapter force every longer pure iterate to collapse immediately to a scaled first action.

Word Classification

The free monoid on two generators $\{L, J\}$ evaluates to operators on $\mathrm{Vec}_{12}\mathbb{Z}$. Every word is classified into one of four cases: empty (identity), pure L-power, pure J-power, or mixed (zero). Law 14L.0 forces this list to be exhaustive and unique, eliminating every additional operator word as a formal defect.

Chapter 37

Rational Multiplication and ε-Splitting

Rational multiplication must be associative, unital, and distribute over addition; these properties are forced by the underlying integer arithmetic. The second half of the chapter derives the ε-splitting lemma: for any positive ε, a quarter-denominator rational δ satisfies $\delta + \delta < \varepsilon$, the key ingredient for combining two Cauchy bounds. Cross-multiplication coherence must survive triple products and distributive expansion, and these same constraints force the small-denominator witness used in the splitting laws.

Rational Multiplication Laws

The multiplication algebra on $\mathbb{Q}$ is forced by reducing every claim to integer associativity, commutativity, and distributivity. No extra multiplicative freedom survives the cross-product setoid.

Step 1.5: Positive reciprocal infrastructure. The analytic Planck block now has a precise target shape, so the next forced arithmetic step is an inversion law that does not overreach. The minimal viable layer is the strictly positive sector of ℚ: positivity can be reflected to the numerator, the numerator can be exposed in successor form, and then denominator and numerator-magnitude can be swapped to produce a reciprocal whose product with the original rational collapses back to 1.

ε-Splitting Laws

For any positive $\varepsilon = a/b$, define $\delta = 1/(4b)$. Then $0 < \delta$ and $\delta + \delta < \varepsilon$. This makes it possible to combine two Cauchy-style bounds into one. The section forces a canonical small witness from the denominator of ε, eliminating arbitrary threshold choices.

Chapter 38

Rational Distance Laws

Every metric space axiom for $d_{\mathbb{Q}}$ is forced by the cross-multiplication setoid on $\mathbb{Q}$. Self-distance is zero (reflexivity), $|x - y| = |y - x|$ (symmetry), the triangle inequality $d(p, r) \leq d(p, q) + d(q, r)$ is an integer-level scaling argument, and translation/multiplicative invariance follow by factoring out common denominator squares. The absolute-value numerator and the cross-multiplication denominators must remain coherent under addition, negation, and multiplication. These constraints force the full metric algebra of $\mathbb{Q}$, including the key bounded-by-ε laws used later in the Cauchy closure arguments.

Metric Axioms

The core metric axioms for $d_{\mathbb{Q}}$ are forced here. Each axiom collapses to integer absolute-value identities together with denominator coherence in the rational setoid.

Triangle Inequality

The triangle inequality $d(p, r) \leq d(p, q) + d(q, r)$ is forced by multiplying the base scaled-numerator inequality through by a common positive factor $s = (b \cdot d) \cdot f$, then regrouping the six resulting terms. No alternative estimate survives once all three distances are expressed over the same positive scale.

Translation Invariance

Adding the same rational to both endpoints cannot change distance: the r-contributed terms cancel exactly, leaving the base difference multiplied by a denominator square f^2. Translation dependence is eliminated by forcing those added terms to cancel on the nose.

Multiplicative Scaling

Multiplying both endpoints by the same rational p scales the distance by $d(p, 0)$. This follows from factoring $Z = ab \cdot \text{baseQR}$, then pulling $|ab|$ apart via the multiplicativity of $|\cdot|$. The scaling law is therefore forced by a single common factor rather than by any separate metric assumption.

Distance Bounds

The key bounding lemma: if $x \leq y + \varepsilon$ and $y \leq x + \varepsilon$ then $d(x, y) \leq \varepsilon$. The proof factors the cross-multiplication into $|d \cdot f| \leq e \cdot bd$ using the absolute-value within-bound lemma. The converse extractions recover one-sided order bounds from a distance certificate, closing the gap between order certificates and metric certificates.

```

The rational distance function is fully operational: triangle inequality, translation invariance, multiplicative scaling, ε-splitting, and distance-order interconversion are all established. Together with the additive and multiplicative order laws from the preceding chapters, $\mathbb{Q}$ is a complete ordered field except for one property: metric completeness. Not every Cauchy sequence of rationals converges to a rational. That deficiency, once named, forces the next construction.

The Archimedean property of $\mathbb{Q}$ must be made explicit so that convergence estimates can quantify "how fast" sequences approach their limits. With Archimedean scaling in hand and the operator span of K_{12} reduced to its canonical (I, J)-basis, the spectral action of the Laplacian completes the rational infrastructure. After that, no further rational law is needed—only the passage to the reals remains.

Chapter 39

Archimedean Scaling

The Archimedean property for $\mathbb{Q}$: given any $\varepsilon > 0$ and any natural number m, there exists $\delta > 0$ such that $\delta \cdot (m+1) < \varepsilon$. This is forced by the existence of denominators that grow faster than linear factors, together with the half-epsilon infrastructure. The required denominator must be forced from the scaling count and the denominator of ε, leaving no arbitrary choice in the witness construction. The resulting witness collapses to the forced half-epsilon bound and supplies the scaling control needed in the Cauchy convergence arguments.

Chapter 40

$\mathbb{Z}$-Span of K_{12} Operators

The identity operator I and the all-ones operator J (which maps every vector to the constant vector of its sum) span a forced sub-algebra of $\mathrm{End}(\mathrm{Vec}_{12}\mathbb{Z})$. Every operator of the form $a{\cdot}I{+}b{\cdot}J$ is uniquely determined by its coefficients (a, b), and composition closes inside the span with the multiplication rule $(a, b){\cdot}(c, d) = (ac,\ ad{+}bc{+}12bd)$. The coefficients are forced by evaluating a single delta vector, which eliminates every alternative representation and fixes composition inside the same span.

Span Infrastructure

The (I, J)-span on Vec_{12} becomes usable only after the identity action, blockwise scaling, and the linear form $aI + bJ$ are pinned down without representational slack.

```
-- § identity operator on Vec12ℤ
I12 : Op
I12 v = v

Chapter 41

Forced Spectral Action of the (I, J)-Span

The $(\mathbf{I}, \mathbf{J})$-span established in Ch. 40 provides normal-form coefficients for every endomorphism of $\mathrm{Vec}_{12}\mathbb{Z}$ belonging to that span. This chapter forces the *spectral decomposition*: every $(a \cdot \mathbf{I} + b \cdot \mathbf{J})$ is forced to act as scalar multiplication by a on sum-zero vectors and by $a + 12b$ on constant vectors, and these two predicates are forced invariant under every span element. The K_{12} Laplacian is then identified as the concrete span element $(12, -1)$, and the full eigenvalue-exhaustion theorem is established: no eigenvalue other than $\lambda = 12$ or $\lambda = 0$ is possible for a nonzero vector. The normal-form coefficients therefore force the spectral action, the Laplacian identification, and finally the exhaustive eigenvalue elimination.

Forced Predicates on $\mathrm{Vec}_{12}\mathbb{Z}$

The two predicates—sum-zero and constant—that will serve as invariant subspaces for the (I, J)-span are defined as Σ-witnesses, ensuring downstream consumers receive constructive content. Only two subspaces survive the later spectral elimination.

```
-- § Sum-zero and constant predicate witnesses on Vec12ℤ
ZeroSumVec12 : Vec12ℤ → Set
ZeroSumVec12 v = sum12ℤ v ≡ 0ℤ

ConstVec12 : Vec12ℤ → Set
ConstVec12 v = Σ ℤ (λ c → Vec12Eq v (constVec12ℤ c))
```

Congruence of linIJ and interpIJ

Before the spectral laws, we establish that the span representation respects pointwise equality—a precondition for transporting results across different witnesses of the same vector. Congruence eliminates representation drift before any spectral fact is transported.

```
-- § linIJ respects Vec12Eq

```

Forced J-Action

The averaging operator **J** acts definitionally as the sum Σ_{12} broadcast to every coordinate. On sum-zero vectors it annihilates; on constant vectors it multiplies by 12. These two actions are the fixed witnesses from which the later span spectrum is forced.

```
-- § Law 14O.0: sum-zero forces J-annihilation
law14O-0-J-sum0 : (v : Vec12ℤ) → ZeroSumVec12 v → Vec12Eq (J12Vec12ℤ v) zeroVec12ℤ
law14O-0-J-sum0 v sum0 =
 (λ _ → sum0) , ((λ _ → sum0) , (λ _ → sum0))

-- § Law 14O.1: constant vectors force J-scaling by 12
law14O-1-J-const : (c : ℤ) → Vec12Eq (J12Vec12ℤ (constVec12ℤ c)) (constVec12ℤ (twelveTimesℤ c))
law14O-1-J-const c =
 (λ _ → sum12-const c) , ((λ _ → sum12-const c) , (λ _ → sum12-const c))
```

Forced Two-Eigenvalue Classification

Every element $a \cdot \mathbf{I} + b \cdot \mathbf{J}$ of the span is forced to act with eigenvalue a on sum-zero vectors (because the **J**-term collapses) and eigenvalue $a + 12b$ on constant vectors (because the sum of a constant vector is $12c$). No third spectral action survives on the forced invariant subspaces.

```

Forced Predicate Invariance Under the (I, J)-Span

Both the sum-zero and constant predicates are forced to be invariant under every element of the (I, J)-span. The sum-zero invariance follows from the forced closed form of $\Sigma_{12}(\text{linIJ } a\ b\ v)$; the constant invariance follows from sum congruence and the eigenvalue structure of Law 14O.3. This eliminates any gap between algebraic normal form and the spectral predicates.

Spectral Package for linIJ

The four forced spectral facts—sum-zero invariance, constant invariance, sum-zero eigenvalue a, constant eigenvalue $a + 12b$—are bundled into a single witness type so that downstream consumers need only one import. Packaging adds no new freedom; it only collects the already-forced facts into a single interface.

Transport from Normal Form to Spectral Facts

Any operator f that possesses a span witness $f = a \cdot \mathbf{I} + b \cdot \mathbf{J}$ inherits all four spectral facts by composing the pointwise equality with the corresponding forced law for linIJ a b. The transport step eliminates any distinction between an abstract span witness and its normal-form representative.

```
-- § Law 14O.11: any f with witness f=(a·I+b·J) inherits the spectral facts

Span Witness Packages

The coefficient pair (a, b) witnessing $f = a \cdot \mathbf{I} + b \cdot \mathbf{J}$ is forced unique by Law 14N.2. We package it together with the spectral facts so that downstream consumers receive a single, canonical witness. All remaining witness multiplicity at the package level is thereby removed.

```
-- § Law 14O.12: span-IJ coefficient witness is forced unique
SpanIJSpectralPackage : Op → Set
SpanIJSpectralPackage f = Σ SpanIJ (λ p → OpEq f (interpIJ p))

Torsion-Free Kernel Upgrade

The kernel constraint $12 \cdot v = \mathbf{J}\, v$ forces all coordinates to share the same 12-multiple. Once the positivity witness $12 = +\mathrm{suc}\ 11$ is supplied, torsion-freeness eliminates all remaining coordinate freedom and forces v itself to be constant. This is the step that collapses the kernel witness from scaled constancy to actual constancy.

```

Eigenvalue Exhaustion

The earlier laws force the constraints for $\lambda = 12$ and $\lambda = 0$; here we force that any eigen-equation can only occur with $\lambda = 12$, $\lambda = 0$, or with the zero vector. The key ingredient is the Laplacian's commutativity with scaling and torsion-freeness over $\mathbb{Z}$. Every further eigenvalue candidate is eliminated as incoherent.

Corrected Ausschlussgesetz

The eigenvalue exhaustion (Law 14O.35) combines with the forced constraint laws (Law 14O.32) to produce the unique coherent eigenvector classification: $\lambda = 12$ forces sum-zero, $\lambda = 0$ forces constant, and every other λ forces the zero vector. The final exclusion law is packaged with no surviving branch left open.

The rational measurement layer expresses the spectral content exactly. Quotients, distances, finite-index operators, coupled and triple K_4 Laplacians, word algebra, and rational order describe the combinatorial data without leaving gaps at the level of explicit calculation. The integer $\alpha^{-1} = 137$ is computed as a Simplex-Euler invariant in Chapter 28; the spectral eigenvalues $\{0, 4\}$ of K_4 are determined; and the 3:1 eigenspace split matches the dimensional signature of relativistic spacetime. These numbers emerge from the graph, not from physics. What the remaining chapters establish is that they cannot emerge from any other source.

What remains is not another finite algebraic law but closure itself. Once the metric structure is explicit, Cauchy data that does not settle inside $\mathbb{Q}$ must be given a legitimate home. The next step is therefore forced completion: the passage from rational measurement to the reals.

Figure 41.1 fixes that transition in one glance. Rational points do not disappear; they embed as constant sequences. What changes is that the metric space is no longer allowed to leak Cauchy processes that have nowhere to land. The closure adds precisely those limit points the rational layer could approach but not contain.

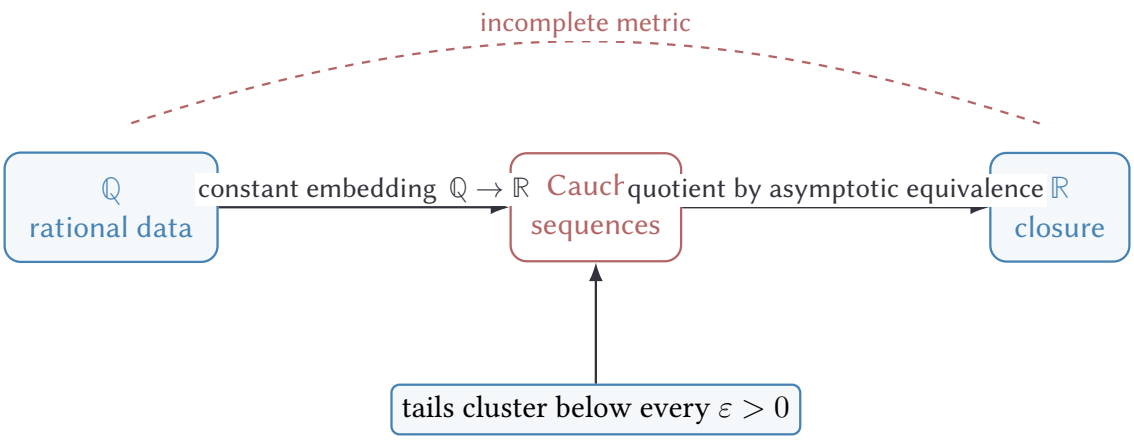

Figure 41.1: Forced Cauchy closure: $\mathbb{Q}$ embeds as constant sequences, while the missing limits of rational Cauchy data are closed inside $\mathbb{R}$.

Chapter 42

Reals as Forced Cauchy Closure over $\mathbb{Q}$

The metric on $\mathbb{Q}$ is incomplete, so Cauchy data cannot remain inside $\mathbb{Q}$ without loss. The reals are therefore forced as the Cauchy closure, with arithmetic and order lifted pointwise through explicit preservation proofs. Every later real operation and law is fixed by that single closure step, with no additional parameters.

Cauchy condition and the real number type

A sequence is Cauchy when, for every rational tolerance $\varepsilon > 0$, all sufficiently late terms cluster within ε of each other. A real number is a sequence carrying a proof of this condition. The embedding $\mathbb{Q} \hookrightarrow \mathbb{R}$ sends each rational to the constant sequence, whose Cauchy proof is immediate from dist$\mathbb{Q}$-const$<\epsilon$. What follows fixes the only admissible entry point from rational metric data to real closure.

Real equivalence and symmetry

Without an equivalence relation, Cauchy sequences are merely sequences: distinct as data, indistinguishable as limits. The passage from sequences to real numbers demands a quotient, and the quotient demands a relation that is reflexive, symmetric, and transitive. Once the rational metric is in place, the only relation that captures "same limit" is asymptotic distance elimination: two sequences are equivalent when their pointwise distance is eventually below every positive ε.

The quotient relation on Cauchy data is forced here: two representatives may describe the same real only when their rational distance is eventually eliminated at every positive scale. Symmetry then removes the residual orientation freedom, since the witnessing distance is already fixed by the symmetry law for $\mathrm{dist}\mathbb{Q}$.

Constraint: Equivalent sequences must have vanishing pointwise distance at every positive scale, or the quotient would identify sequences with distinct limits.

Elimination: Any identification weaker than pointwise ε-convergence fails to separate distinct limits; any identification stronger collapses sequences that converge to the same value. The only surviving relation is $x \simeq_{\mathbb{R}} y$ iff for every $\varepsilon > 0$ there exists N such that $\mathrm{dist}\mathbb{Q}(x_n, y_n) < \varepsilon$ for all $n \geq N$. Symmetry follows from $\mathrm{dist}\mathbb{Q}$-sym.

Consequence: The equivalence relation is locked. Reflexivity and transitivity are inherited from the metric; symmetry is proved below. No weaker or stronger identification survives.

Addition on ℝ

The Cauchy closure carries sequences, but sequences without operations are inert. If addition is not extended from ℚ to ℝ, the real field never forms, and the later spectral constants have no additive home. The extension is forced to be pointwise: any other rule would sever the sum from the underlying rational terms and destroy the Cauchy property that defines the closure.

Addition on ℝ is forced to be the pointwise lift of rational addition: any other operation would detach the real structure from the Cauchy witnesses that generate it. The proof eliminates instability by quartering ε, pulling Cauchy moduli from both summands, and collapsing the total distance through distℚ-triangle together with the two translation laws for distℚ.

Constraint: Two Cauchy error budgets must be merged without overflow.

Elimination: Quarter ε to eliminate cross-term overflow, extract moduli independently from each summand, and drive the total distance below ε via the triangle inequality. Any coarser budget allocation fails the Cauchy condition.

Consequence: Real addition is the unique Cauchy-compatible pointwise lift. No alternative survives.

Negation, subtraction, and constants

Once addition has entered the closure, negation is forced by the demand for additive inverses: without negation, the reals would be a monoid rather than a group, and the later additive algebra laws would have no cancellation target. The key enabler is that the rational metric is already sign-invariant (distℚ-neg), so negating every term of a Cauchy sequence preserves the Cauchy property without any additional ε-budget.

Negation must preserve real structure because the rational metric is invariant under sign reversal through distℚ-neg. Subtraction therefore has no separate freedom beyond addition

with negation, and the distinguished constants $0_{\mathbb{R}}$ and $1_{\mathbb{R}}$ are forced as the direct images of the corresponding rational constants.

Constraint: Subtraction must decompose as addition-with-negation so that no independent Cauchy proof is needed.

Elimination: Pointwise rational negation is the only operation whose Cauchy proof inherits from $\mathrm{dist}\mathbb{Q}$-neg without additional witness data. Any alternative negation either breaks the Cauchy property or fails to invert addition. Subtraction reduces to $x + (-y)$; the constants 0 and 1 embed as constant sequences.

Consequence: The additive group structure is complete. No further algebraic primitive is needed until multiplication.

Additive algebra laws

With addition, negation, and the distinguished constants in place, the additive algebra must now be shown to obey the same laws as $\mathbb{Q}$—commutativity, associativity, identity, and inverse. If any of these failed, the real field would diverge from the rational one it was built to complete, and the later spectral identities could not be transported from $\mathbb{Q}$ to $\mathbb{R}$.

The additive algebra on $\mathbb{R}$ cannot differ from the rational algebra already fixed pointwise on representatives. Each law is forced by the same elimination pattern: take threshold $N = 0$,

invoke the corresponding rational identity, and collapse the resulting distance to zero via distℚ-≃0.

Constraint: Every additive law must hold up to $\simeq_{\mathbb{R}}$, not merely pointwise, so that the laws descend to the quotient.

Elimination: For each law, the Cauchy threshold collapses to $N = 0$: the corresponding rational identity eliminates all distance between the two sides at every index. No finite-prefix correction survives.

Consequence: Commutativity, associativity, identity, and inverse are forced. The additive group is an abelian group over $\mathbb{R}$.

Eventual boundedness and multiplication

Cauchy closure, once created, cannot remain a purely additive object. If multiplication is left outside the closure, the real field collapses to a module over $\mathbb{Q}$ and loses the self-interaction that every later physical quantity depends on. But admitting multiplication forces a new constraint: the product of two convergent sequences need not converge unless both factors are eventually bounded. Boundedness is therefore not an optional refinement; it is the gate through which multiplication enters, and without it the Cauchy property of the product cannot even be stated.

Multiplication cannot be admitted until eventual boundedness is extracted from every Cauchy representative, because product control requires fixed bounds on one factor while the other factor oscillation is eliminated. The proof first forces a tail bound by evaluating the Cauchy condition at $1_{\mathbb{Q}}$, then decomposes the product distance into two terms and drives each term below $\varepsilon/4$ by the same δ-scaling discipline used throughout the metric development.

Constraint: Without bounded tails, the product distance $|f_n g_n - f_m g_m|$ contains a term proportional to an unbounded factor, so no uniform ε-control exists.

Elimination: Extract a tail bound B from the Cauchy condition at tolerance 1, eliminating unbounded growth beyond that tail. Then decompose the product distance via the identity $fg - f'g' = f(g-g') + g'(f-f')$ and drive each summand below $\varepsilon/4$ using the bound and δ-scaling. Any sequence without a finite tail bound is excluded.

Consequence: Multiplication enters $\mathbb{R}$ with its Cauchy property locked to the same ε-quartering discipline that governs addition. No alternative entry survives.

```

```

Step 2: Real Multiplication. $\cdot_{\mathbb{R}}$ multiplies Cauchy sequences pointwise. The Cauchy property of the product uses eventual boundedness plus δ-scaling to control the error.

Multiplicative algebra laws

Addition forms a group, but a group alone cannot encode physics: the coupling constants that will emerge from K_4 are multiplicative invariants, and the spectral identities interleave products with sums. If multiplication on $\mathbb{R}$ does not obey the same algebra as multiplication on $\mathbb{Q}$, the constants lose their ring-theoretic home and the later observables cannot be defined.

Once multiplication is forced on representatives, its algebraic laws have no remaining freedom: each one is the pointwise lift of the corresponding rational law. The witness pattern is

again uniform, with threshold $N = 0$, the rational identity at stage n, and immediate elimination of the induced distance by $\mathrm{dist}\mathbb{Q}$-$\simeq 0$.

Constraint: Every multiplicative law must hold up to $\simeq_{\mathbb{R}}$ so that the ring structure descends to the Cauchy quotient.

Elimination: For each law, the Cauchy threshold collapses to $N = 0$: the corresponding rational identity eliminates all distance between the two sides at every index, and $\mathrm{dist}\mathbb{Q}$-$\simeq 0$ closes the gap. No alternative threshold or identity survives.

Consequence: Commutativity, associativity, identity, and distributivity are forced. Together with the additive group, the reals are a commutative ring—the minimal structure that can host the spectral constants.

Congruence of multiplication and addition

A ring whose operations depend on the choice of representative is no ring at all: congruence is the bridge that turns operations on Cauchy sequences into operations on reals. Without it, the field structure collapses back to raw sequence manipulation, and the spectral constants would vary with the representative chosen—an unphysical catastrophe.

Congruence removes the last representative dependence: addition and multiplication are admissible on reals only if equivalent Cauchy data are sent to equivalent results. Addition follows the already forced additive control, while multiplication repeats the product decomposition with mixed representatives and uses eventual bounds plus δ-scaling to eliminate both error terms.

Constraint: Both operations must map $\simeq_{\mathbb{R}}$-equivalent inputs to $\simeq_{\mathbb{R}}$-equivalent outputs, or the quotient construction fails.

Elimination: For addition, triangle-inequality elimination suffices. For multiplication, decompose the product difference via the identity $xz - x'z' = x(z - z') + (x - x')z'$, then scale each summand by an eventual bound from texttIsCauchy-eventually-bounded. Any operation that fails this decomposition is excluded from the quotient.

Consequence: Addition and multiplication are well-defined on the Cauchy quotient. The reals now form a genuine commutative ring, not merely a ring of sequences.

Asymptotic Order on ℝ

A field without order cannot host inequalities, and inequalities are the language of physics: every bound, every spectral gap, every convergence statement is an order statement. But reals are equivalence classes of Cauchy sequences, and finite-prefix comparisons do not survive the passage to the quotient. The only order that does survive is asymptotic: a comparison that holds on every tail, for every positive margin.

Order on ℝ is forced to be asymptotic: finite prefixes cannot survive quotient formation, so only eventual rational comparison with arbitrary positive margins remains admissible. The unique strict and non-strict order notions compatible with representative elimination under $\simeq_{\mathbb{R}}$ are fixed below.

Constraint: Order must be compatible with the Cauchy quotient: if $x \simeq_{\mathbb{R}} x'$ and $x \leq_{\mathbb{R}} y$, then $x' \leq_{\mathbb{R}} y$. Any order depending on a finite prefix is shattered by re-choosing the representative.

Elimination: Any order definition depending on a finite prefix is shattered by re-choosing the representative. The only surviving definitions are: $x \leq_{\mathbb{R}} y$ iff for every $\varepsilon > 0$ there exists N such that $x_n \leq y_n + \varepsilon$ for all $n \geq N$; and $x <_{\mathbb{R}} y$ iff there exists $\varepsilon > 0$ with the same tail comparison. Every prefix-dependent alternative is eliminated.

Consequence: Twelve order laws are forced—reflexivity, transitivity, antisymmetry, congruence under $\simeq_{\mathbb{R}}$, and additive monotonicity—closing the ordered-field scaffold required by the spectral constants.

Law 23.1: Non-strict asymptotic order

Non-strict order is forced by eventual ε-comparison for every positive rational margin. Any weaker condition leaves room for prefix dependence, and that dependence is already excluded by the quotient from Cauchy representatives to reals.

```
-- § Non-strict real order: eventual ϵ-approximation
infix 4 _≤ℝ_ _<ℝ_

record _≤ℝ_ (x y : ℝ) : Set where
 field
  leReal : (ϵ : ℚ) → (0ℚ <ℚ ϵ) → Σ ℕ (λ N → (n : ℕ) → N ≤ n → (seq x n) ≤ℚ ((seq y n) +ℚ ϵ))

-- § Type alias for non-strict real order
≤ℝP : ℝ → ℝ → Set
≤ℝP = _≤ℝ_
```

Law 23.2: Strict asymptotic order

Strict order is forced by a positive rational witness that survives on a tail. This eliminates vanishing separation and fixes strictness as stable asymptotic margin rather than finite-stage fluctuation.

```
-- § Strict real order: witnessed separation
record _<ℝ_ (x y : ℝ) : Set where
 field
  ltWitness : Σ ℚ (λ ϵ → (0ℚ <ℚ ϵ) × Σ ℕ (λ N → (n : ℕ) → N ≤ n → ((seq x n) +ℚ ϵ) ≤ℚ (seq y n)))
```

Law 23.3: Strict order forces non-strict order

Every strict witness forces non-strict order once the positive gap is forgotten after it has done its work. The margin survives only as an intermediate constraint and is then eliminated from the final asymptotic comparison.

```
-- § Strict order implies non-strict by forgetting the margin

  }
```

Law 23.4: Equivalence forces non-strict order

distance bounds eliminate any persistent asymptotic gap. The resulting Representative equivalence forces non-strict order because eventual distance bounds eliminate any persistent asymptotic gap. The resulting order law therefore remains invariant under replacement by an equivalent Cauchy representative.

```

   }
```

Transitivity of Strict Order

Strict asymptotic separation must compose whenever two positive margins occur in sequence. The remaining freedom that an intermediate witness could block composition is eliminated, forcing strict order to survive transitive chaining.

Law 23.5: Strict order is transitive

Witness margins compose after controlled shrinking. Quartering eliminates overflow in the combined error budget and forces one surviving positive margin for the composite comparison.

Congruence of Strict Order under $\simeq_{\mathbb{R}}$

If strict order depends on which representative carries it, it is not an order on real numbers—it is merely an order on sequences. The Cauchy quotient annihilates any comparison that cannot survive a representative swap. The proof below shows that strict order does survive, by quartering the original witness gap and absorbing the equivalence corrections into the margin.

Strict order must survive elimination of representative choice, otherwise it would not descend from Cauchy data to the real quotient. That dependence is removed by transporting a strict witness across equivalence on both sides while preserving a positive asymptotic gap.

Constraint: The positive gap ε_0 that witnesses $x <_{\mathbb{R}} y$ must remain strictly positive after both sides are perturbed by representative change.

Elimination: Quarter ε_0 into four budgets, spend two on transporting through $x \simeq x'$ and $y \simeq y'$, and retain a strictly positive remainder as the new witness. Any budget that fails to leave a positive remainder is eliminated; the quartering is the unique surviving allocation.

Consequence: $<_{\mathbb{R}}$ is well-defined on the Cauchy quotient. No comparison can be fabricated or destroyed by representative choice.

Law 23.6: Strict order is invariant under equivalence

The witness margin survives both equivalence corrections by repeated quartering. This eliminates representative drift while preserving a strictly positive asymptotic gap.

Reflexivity of $\leq_{\mathbb{R}}$

Any admissible asymptotic order must retain self-comparison. The positive margin only relaxes the comparison further, so any failure of reflexivity would contradict the order structure already forced on representatives.

Law 23.7: Non-strict order is reflexive

Reflexivity is forced because every positive margin preserves the same sequence pointwise. Self-comparison must therefore hold on every tail with no residual freedom.

```
-- § Reflexivity of ≤ℝ
≤ℝ-refl : (x : ℝ) → x ≤ℝ x
≤ℝ-refl x = record
 { leReal = λ ϵ ϵpos →
   zero , (λ n _ →
    ≤ℚ-add-nonneg-right (seq x n) ϵ (<ℚ→≤ℚ ϵpos))
 }
```

Transitivity of $\leq_{\mathbb{R}}$

Eventual upper bounds are forced to compose across an intermediate real. The only remaining work is to control the accumulated margin so that the composite comparison still fits inside the requested tolerance.

Law 23.8: Non-strict order is transitive

Two eventual $\varepsilon/4$ bounds are forced into one eventual ε bound. Associativity eliminates ambiguity in how the margins accumulate along the composite comparison.

Antisymmetry of $\leq_{\mathbb{R}}$

Mutual asymptotic domination must collapse to equality of reals. If two representatives eventually bound each other at every positive margin, no residual distance can survive in the quotient.

Law 23.9: Mutual non-strict order forces equivalence

Two-sided eventual bounds force asymptotic distance below every positive margin. What survives is exactly equivalence of the underlying Cauchy representatives.

Congruence of $\leq_{\mathbb{R}}$ under $\simeq_{\mathbb{R}}$

Strict order has been saved. But if non-strict order cannot survive the same representative swap, the ordered-field structure is only half-built: reflexivity and transitivity would apply to sequences, not to reals. The rescue is simpler than for strict order, because $\leq_{\mathbb{R}}$ can be transported by composing with the equivalence-induced bounds that already exist.

Non-strict order must also survive elimination of representative choice, otherwise order would not descend to the real quotient. The only admissible transport is composition with the equivalence-induced order bounds already forced above.

Constraint: $\leq_{\mathbb{R}}$ must be well-defined on the Cauchy quotient: if $x \simeq x'$ and $y \simeq y'$, then $x \leq y$ implies $x' \leq y'$.

Elimination: Chain $x' \leq x$ (from $x \simeq x'$), $x \leq y$ (given), and $y \leq y'$ (from $y \simeq y'$) via transitivity. Any path that fails to compose through the equivalences is eliminated; the transitive chain is the only surviving route.

Consequence: $\leq_{\mathbb{R}}$ descends to the quotient. Together with $<_{\mathbb{R}}$, the full order structure is representative-independent.

Law 23.10: Non-strict order is invariant under equivalence

The congruence law is forced by composing equivalence-induced bounds on the left and right. No additional order data survives elimination.

Right Additive Monotonicity of $\leq_{\mathbb{R}}$

An ordered ring in which addition can reverse an inequality is useless for physics: every energy shift, every spectral translation depends on monotonicity under addition. Adding a common term to both sides of an inequality must not destroy the comparison, or the later additive transport laws for the physical constants collapse.

Right addition must preserve asymptotic order. Once addition has been forced on reals, adjoining the same summand on the right cannot create a new comparison failure.

Constraint: $x \leq y$ must imply $x + z \leq y + z$ for every real z.

Elimination: Lift pointwise rational monotonicity through $+\mathbb{Q}$-mono-$\leq$-right, then use ε-margin associativity to eliminate ambiguity in the placement of the surviving margin. Any alternative placement breaks the tail bound.

Consequence: Both right and left monotonicity are forced, completing the twelve-law ordered-field scaffold.

Law 23.11: Right addition preserves non-strict order

Right monotonicity is forced by pointwise rational monotonicity. Associativity eliminates ambiguity in the placement of the surviving ε-margin.

The numerical machinery is in place. Natural numbers, integers, rationals, reals, order, distance, scaling, and spectral operators have all been forced from the surviving structure rather than imported from outside it. The full language required to evaluate K_4 quantitatively is established.

The final step is assembly. The invariants already derived must be gathered into a single verified record so that the physical correspondence can be inspected as computation rather than impression.

Part VI

Physics from K_4

The arithmetic, spectral theory, and measurement formalism built in the preceding chapters constitute the apparatus needed to translate K_4's combinatorial invariants into numbers. This part performs that translation.

Nothing new is assumed. The vertex count, edge count, Euler characteristic, and Laplacian eigenvalues of K_4 are assembled into a verified computation record. Each entry is a definitional equality closed by the Agda type system. The numerical values that result—including the inverse fine-structure constant $\alpha^{-1} = 137$—are consequences of the structure derived in Parts I through IV, not inputs chosen to match them.

This is the methodological boundary that matters for the numerology question. The numerical match is not being used here as evidence for the structure. The structure has already been forced by the elimination chain. What appears in this part is the evaluated consequence of that survivor. The burden is therefore not pattern recognition but invariance under the chain of eliminations that left no adjustable parameter standing.

The reader should therefore keep two claims sharply apart. The theorem-level claim is internal to the formal system: given the derivation already established, these equalities reduce and these numbers compute. The interpretation-level claim is external: some of these computed values may be read as physically meaningful because they align with measured observables. The first claim is proved here. The second is discussed here, but it is not smuggled into the proof.

Whether these numbers illuminate the structure of physics or merely reproduce it is a question the record itself cannot settle. That is an interpretive burden, not a formal one. But the record itself is exact, machine-verified, and fully open to inspection.

Chapter 43

Natural-Number Division Infrastructure

The combinatorial laws of K_4 require exact natural-number division, yet the safe base environment does not provide the needed machinery. This chapter therefore fixes the minimal arithmetic infrastructure that survives the safety constraints and still forces every later combinatorial count to remain mechanically decidable.

Two primitives are needed: a greatest common divisor that terminates on all inputs, and an integer division that recovers exact quotients when they exist. Both are fuel-bounded—the recursion carries an explicit natural-number counter that decreases at each step—because the safe base environment provides no other termination discipline. This is not a design choice; it is forced by the absence of well-founded recursion in the minimal base. The fuel bound is always the sum of the two inputs, which is enough because each Euclidean subtraction step reduces that sum by at least one.

Constraint: Termination of the Euclidean algorithm on arbitrary naturals requires an explicit fuel counter in the safe base.

Elimination: Without structural recursion on an explicit fuel counter, no terminating implementation of the Euclidean algorithm survives the safe base. The only surviving form is a three-argument gcd-fuel recurrence that subtracts the smaller input from the larger at each step, consuming one unit of fuel, and a div-fuel recurrence that counts how many times the divisor fits.

Consequence: Both primitives are total and structurally decreasing in fuel. Every downstream combinatorial identity reduces to refl once the fuel evaluates.

```

... | true = refl
... | false = refl

-- § GCD with canonical fuel
gcd : ℕ → ℕ → ℕ
gcd m n = gcd-fuel (m + n) m n
```

Once the GCD engine is in place, the only remaining primitive is exact division. A rational quotient n/d must be decomposable into a whole-number part whenever d divides n; otherwise the correction fractions in the physics chapter would remain opaque to computation. Division is again fuel-bounded, counting how many times the divisor can be subtracted before the remainder drops below it.

```

Canonical Quotient Data and Reduced Witnesses

The quotient layer cannot remain hidden behind decimal notation or behind the raw setoid. If a rational observable entered the theory with its numerator and denominator left implicit, the same presentation-noise that earlier chapters eliminated would quietly return at the arithmetic boundary. The rational layer must therefore expose its own surviving ledger.

Part IV already forced admissible observables to collapse to canonical base content. That pressure now reaches the quotient level. Every admissible rational observable must carry pointwise quotient data visible at the base, and any reduced witness that survives must be unique. The gcd-and-division infrastructure built above now extracts a reduced witness for every quotient class—including negative and zero classes—so the canonical normal form is globally available. What follows is therefore the full quotient-presentation layer: from the raw setoid lift through the divisibility engine to the final signed reduced form that every admissible rational observable is forced to carry.

Constraint: A rational observable may not hide its quotient structure behind the equality relation. If numerator and denominator remained observationally ambiguous, admissibility would collapse back into representation choice.

Elimination: Any observable structure that hides its quotient fields behind the equality relation is eliminated by the admissibility constraint. The only surviving pathway lifts rational values into Set_ω, packages their explicit quotient data, and then lifts that presentation pointwise along admissible observables. Reduced witnesses are forced as positive numerator/denominator presentations together with coprimality, and uniqueness is forced by the quotient fields themselves. The same mechanism extracts a canonical reduction candidate from the raw fields by dividing numerator and denominator by their computed gcd.

Consequence: Every rational class now admits a signed reduced normal form—proved via the canonical-reduction-form theorem that splits on sign, reduces the magnitude through the gcd engine, and lifts the result through negation compatibility. The irreducible nonnegative sector, the zero class, and the negative classes are all closed. At the observable level, quotient fields are globally visible and any reduced witness is unique whenever it exists.

Quotient presentation and field uniqueness

Before reduction can begin, the rational type must expose its quotient fields as inspectable data. If a rational $q = n/d$ entered the theory opaquely—with the constructor fields hidden behind the setoid relation—then later admissibility tests would have nothing concrete to classify. The lift into Set_ω makes rational observables composable with the drift framework, and the presentation record simply reads off the constructor fields that already exist. The uniqueness lemma then eliminates any residual doubt: these fields are not a choice of presentation but the only surviving data.

rational-fields-unique (n / d) n₁ n₂ d₁ d₂ refl refl = refl , refl
```

Reduced witnesses and irreducibility

Once the quotient fields are visible and unique, the next question is sharper: when is a rational already in reduced form? The answer is forced by coprimality. A quotient n/d is *irreducible* when $\gcd(|n|, d) = 1$—when the numerator magnitude and the denominator share no factor beyond one.

A *reduced rational witness* makes this concrete. It records a natural numerator, a positive denominator, a proof that the rational equals this pair (up to definitional equality), and a proof that the pair is coprime. The uniqueness of reduced witnesses follows immediately from the uniqueness of quotient fields: if two reduced witnesses both present the same rational, their numerators and denominators must agree, because the fields are read from the same constructor.

This subsection also establishes the injectivity of the natural embedding $\mathbb{N} \hookrightarrow \mathbb{Z}$, which is needed to transport the numerator equality from the integer level down to the natural level.

Arithmetic lemmas and exact division

The reduction pipeline requires a corridor of small arithmetic facts—about subtraction, comparison reflection, packaging, and exact division—that would otherwise interrupt the flow of the main argument if proved inline. None of these is surprising. Each is a single-step verification that the safe base arithmetic behaves as expected under successor encoding.

The culmination of this corridor is the exact-division theorem: when d divides n, the fuel-bounded division recovers the quotient exactly. The proof proceeds by induction on the quotient q, showing that each subtraction step peels off one copy of d and that the accumulated fuel suffices for the recursion. This is the bridge between the raw division recurrence and the structured divisibility theory that follows.

Positive divisibility theory

Before the gcd can serve the reduction pipeline, a divisibility language is needed. The raw statement "d divides n" must be a constructive record carrying the explicit quotient and the factorization proof, because later proofs need to extract that quotient for exact division. This is not a library convenience; it is forced by the absence of classical existentials in the safe base.

The $\mathrm{Divides}^+$ record captures exactly this: a positive divisor d, a quotient, and a proof that $n = q \cdot d$. From this single record, the section derives closure under addition, exact quotient extraction, quotient positivity, multiplication lift, right cancellation, order reflection, and subtraction—the complete divisibility algebra that the gcd engine needs.

Constraint: The gcd proofs require divisibility witnesses that carry computational content (the quotient), not merely propositional existence.

Elimination: Any divisibility witness that lacks computational content—carrying only propositional existence without an explicit quotient—is eliminated by the downstream gcd

proofs. The only surviving form is a record Divides⁺ d n with field quotient⁺ and factorization proof. Closure under +, −, multiplication, and cancellation follows.

Consequence: Every later divisibility argument reduces to record operations on Divides⁺. No ad hoc arithmetic witness is needed downstream.

The factor constraints above show that divisibility by a product forces each factor to be trivial when the product divides a single copy of one factor. This is the positive-integer analogue of the familiar number-theoretic fact that if $ab \mid b$, then $a = 1$. With this in hand, the machinery compares quotients: if d divides both m and n and $m \leq n$, then the stored quotient for m is at most the stored quotient for n.

GCD engine: common-divisor preservation, output divisibility, and positivity

The Euclidean gcd is defined, but a bare recurrence carries no force. Three properties must be forged before the gcd can serve the reduction pipeline:

Common-divisor preservation. Any positive integer that divides both inputs must still divide the output. This is the "upward" direction: known divisors survive the algorithm. The proof proceeds by mutual structural recursion, tracking divisibility through each subtraction step via the already established divides⁺-∸-≤ lemma.

Output divisibility. Conversely, if the gcd output is positive, it divides both inputs. This is the "downward" direction: the output itself is a common divisor. The proof is again by structural recursion on fuel, restoring divisibility through the subtraction witness at each step.

Positivity. Whenever at least one input is positive, the gcd output is also positive. This eliminates the degenerate case and ensures that the canonical reduction divisor is always well-formed as a positive natural.

Together, these three properties force the gcd to behave as the *greatest* common divisor in the usual sense: it divides both inputs, and every other common divisor divides it.

The inductive core of the gcd engine is established: for any fuel level sufficient to reach termination, the positive output divides both inputs. The remaining step generalises this to the canonical fuel formula $\mathrm{slack} + (m + n)$, which always provides enough iterations. This is the interface consumed by the rational reduction machinery above.

Canonical reduction candidate and divisibility

The gcd engine and the divisibility theory are both in place. The canonical reduction candidate is therefore forced: given a rational $q = n/d$, compute $g = \gcd(|n|, d)$, and define the reduced numerator as $|n|/g$ and the reduced denominator as d/g. The "candidate" is not a guess; it is the unique pair obtained by dividing out the maximal common factor.

Three properties must survive. First, the canonical divisor g is itself positive—forced by the gcd-positivity theorem on the positive denominator. Second, the $\mathbb{N}$-view of the divisor equals the computed gcd—a bookkeeping identity that eliminates the successor-encoding detour. Third, the divisor divides both the numerator magnitude and the denominator—forced by the output-divisibility theorem already established for the gcd engine.

Constraint: The reduction candidate must be computable from the raw fields and must preserve the rational class up to $\simeq_{\mathbb{Q}}$. Any alternative decomposition would reintroduce presentation freedom.

Elimination: Any reduction candidate not computable from the raw fields, or failing to preserve the rational class up to $\simeq_{\mathbb{Q}}$, is eliminated. The unique surviving candidate is canonical-reduction-divisor $= \mathrm{mk}\mathbb{N}^{+}(\gcd(|n|, d) - 1)$. The numerator and denominator are then forced by exact division. Positivity, value agreement, and divisibility follow from the candidate's definition.

Consequence: The candidate is well-defined and the gcd divides both fields. The factorization and coprimality proofs that follow proceed from concrete divisibility witnesses.

Factorization, coprimality, and witness stabilization

The canonical reduction divisor now divides both the numerator magnitude and the denominator. The next forced step is to show that dividing out the gcd produces a coprime pair—so that the candidate is genuinely reduced—and that the entire candidate stabilizes on any input that is already reduced.

Factorization is read directly from the exact-division infrastructure: since the gcd divides both fields, exact division recovers the quotients, and the original fields are the product of quotient times divisor. Coprimality then follows by contradiction: any common divisor of the reduced pair would lift, through multiplication by the gcd, to a common divisor of the *original* pair that exceeds the gcd itself—which contradicts the maximality of the gcd.

Stabilization completes the picture. If the input is already irreducible, the gcd is 1, division by one leaves the fields unchanged, and the candidate collapses to the original witness. This guarantees that the reduction pipeline is idempotent: applying it twice yields the same result as applying it once.

Constraint: Without coprimality, the "reduced" candidate might still hide common factors, and the uniqueness guarantee downstream would fail.

Elimination: Factor both fields through exact division; eliminate any putative common divisor by lifting it back through the gcd—where it is absorbed; eliminate instability by specializing to divisor = 1. The candidate survives all three tests.

Consequence: The canonical candidate is a genuine reduced pair. The reduced witness is idempotent. Every later reference to "the reduced form" is unambiguous.

The gcd machinery has confirmed that the canonical divisor is one, and the field-extraction lemma locks the numerator and denominator of the reduced witness to the original quotient fields. These are bookkeeping results—they do not change the mathematical content, but they allow every subsequent proof to refer to the reduced form without re-deriving the field correspondence each time.

The next step converts a reduced witness into a full irreducibility certificate. Once this is in hand, any rational that admits a reduced witness is provably in lowest terms, and no further simplification is possible.

Normal forms and sign handling

The canonical reduction machinery so far operates on magnitudes: it divides a natural numerator and a positive denominator by their gcd. But a rational number is not a magnitude—it carries a sign. The ReducedRationalForm record captures the quotient-level normal form for nonnegative classes, where the numerator is still a natural number and the equivalence is up to $\simeq_{\mathbb{Q}}$ rather than raw definitional equality. This weaker formulation is forced because gcd-reduction may change the concrete numerator and denominator while preserving the rational class.

For genuinely arbitrary classes including negative ones, a SignedReducedRationalForm extends the nonneg form by allowing the numerator to be an integer. The bridge between the two is the sign-transport infrastructure: negation preserves rational equivalence (-ℚ-resp-≃), and the magnitude of a negated embedded natural is still the original natural (magℤ-neg-fromℕℤ). These two facts together allow a negative class $(-n)/d$ to be reduced by first reducing $(+n)/d$ and then transporting the result through negation.

Constraint: Negative rationals cannot be reduced by the nonneg pipeline directly; their sign must be factored out, the magnitude reduced, and the sign restored.

Elimination: Any normal form that fails to cover the negative sector is eliminated by the sign-transport constraint. The only surviving forms are ReducedRationalForm for the nonneg sector; SignedReducedRationalForm as the signed generalisation; reduced-form→signed as the canonical embedding; and -ℚ-resp-≃ plus magℤ-neg-fromℕℤ as the sign-transport lemmas.

Consequence: Every nonneg form lifts to a signed form. Every negative class is reduced by negation transport. The zero class is trivially nonneg. Together, these three cases cover all of ℚ.

Global reduction theorems

The individual components—coprimality, factorization, sign handling, nonnegative witnesses—are all in place. What remains is to forge them into the global theorem: every rational class, regardless of sign, admits a canonical signed reduced form.

The route is forced. For nonnegative numerators, the factorization data is already available: the gcd divides both numerator magnitude and denominator, the candidate quotients are coprime, and the factorization record can be assembled outright. For negative numerators, the argument proceeds by negation transport: the positive representative $|n|/d$ is reduced first, and the result is then carried back through -ℚ-resp-≃ and magnitude-invariance of negation on embedded naturals. The zero class collapses immediately.

Constraint: Without a global theorem covering all three sign cases, the bridge chapter would need ad hoc case splits at every correction fraction.

Elimination: Each sign case is handled and eliminated in turn: the nonnegative factorization is packaged into CanonicalReductionFactorization, the quotient-level ReducedRational-

Form is derived, the lift to SignedReducedRationalForm closes the nonneg case, and the negative case is eliminated by reducing the negation and transporting the result. No sign case escapes.

Consequence: canonical-reduction-form is total on all of ℚ: zero, positive, and negative classes. The downstream physics chapters may now invoke reduced quotient data without case analysis.

Observable quotient layer

The class-level reduction is complete: every rational carries a signed reduced form. But the physical theory does not touch rationals in isolation. It touches *admissible rational observables*—functions from drift states into $\mathbb{Q}$ that already survive the admissibility filter. If quotient data were not lifted pointwise along these observables, the bridge chapter would be forced to re-derive the presentation at every call site, and the uniqueness guarantee would dissolve into ad hoc casework.

The lift is immediate. An admissible rational observable already assigns a rational value at each drift state. Reading off the constructor fields at each state gives the canonical pointwise presentation; the uniqueness of those fields then propagates pointwise. Reduced witnesses are similarly lifted: a reduced observable carries a reduced witness at every state, and whenever two such witnesses exist, they agree pointwise because the class-level uniqueness theorem already forces agreement field by field.

Constraint: If quotient fields were not globally visible on admissible observables, the correction fractions would lack a canonical numerator/denominator decomposition at each measurement point.

Elimination: Any observable layer that fails to expose quotient data pointwise is eliminated by the admissibility constraint. The only surviving form lifts RationalPresentation and ReducedRationalWitness pointwise along AdmissibleRationalObservable, inheriting uniqueness from the class-level theorems.

Consequence: The bridge chapter may now invoke quotient data and reduced witnesses at any drift state without re-deriving them. The observable quotient layer is closed.

Chapter 44

K_4 Physics Constants Layer

Once the simplex cardinality is fixed at $V = 4$, every combinatorial constant attached to K_4 is already determined. This chapter eliminates parameter freedom by computing edge counts, face counts, spectral constants, and cycle data directly from that forced cardinality, with each law collapsing to definitional equality.

That rigidity must not be overstated. Two different kinds of sentence appear in what follows, and they answer to different standards.

The first kind is theorem. A theorem here is an internal statement of the formal development: a count, spectrum, or equality that Agda closes by reduction. When this chapter proves that a quantity on K_4 is 4, or 6, or 137, the claim is purely structural. It says only that these numbers are forced by the previously derived object.

The second kind is interpretation. Interpretation begins only when one asks whether a formally forced invariant should be read as a physical observable, a coupling, a mass ratio, or a dimensional constant. That move is not part of the theorem. It is a separate act of comparison between the formal survivor and the measured world.

Constraint: The numerology objection gains force precisely when theorem and interpretation are allowed to blur. If a computed invariant is described as physically significant before the formal status of the computation is fixed, the reader can rightly suspect that the target meaning guided the construction.

Elimination: Any methodology that blurs the boundary between theorem and interpretation is eliminated: it reintroduces the numerology objection. The only surviving discipline keeps the registers separate. First the invariant is computed as a theorem internal to the K_4 record. Only afterward is the possible physical reading stated as an interpretation of that already-fixed value. In this chapter, proofs close in the first register; comparisons to measurement are explicitly marked as belonging to the second.

Consequence: The formal content of the chapter stands or falls independently of any physical interpretation. If an interpretation later fails, the theorem remains proved. If an interpretation later succeeds, it succeeds because it reads a pre-existing invariant rather than because the invariant was engineered to fit it.

Simplex invariants

The first layer fixes the bare tetrahedral invariants forced by $V = 4$. Edge count, face count, degree, and Euler characteristic are not introduced independently; each is the unique value surviving the standard simplex formulas.

```
-- § Vertex count of K4 (= simplex-vertices from Tier 5)
vertexCountK4 : ℕ
vertexCountK4 = simplex-vertices

-- § Edge count: E = V(V−1)/2
edgeCountK4 : ℕ
edgeCountK4 = (vertexCountK4 * (vertexCountK4 ∸ 1)) divℕ 2

-- § Face count: F = V(V−1)(V−2)/6
faceCountK4 : ℕ
faceCountK4 = (vertexCountK4 * (vertexCountK4 ∸ 1) * (vertexCountK4 ∸ 2)) divℕ 6

-- § Vertex degree: deg = V − 1
degree-K4 : ℕ
degree-K4 = vertexCountK4 ∸ 1

-- § Euler characteristic: χ = V + F − E
eulerChar-computed : ℕ
eulerChar-computed = (vertexCountK4 + faceCountK4) ∸ edgeCountK4

-- § Law 16B-0: E = 6
law16B-0-edges : edgeCountK4 ≡ 6

```

Every combinatorial constant of K_4 is fixed by definitional equality: vertex count, edge count, face count, degree, Euler characteristic, spectral width, and cycle data. The ledger is sealed. What remains is to show that these constants determine a unique formal representation record—that no second assignment of fields could survive the same constraints.

The numbers so far. At the theorem level, K_4 has produced $V = 4$, $E = 6$, an eigenvalue ratio 3:1, and the combinatorial invariant $\alpha^{-1} = 137$. None of these numbers were adjusted. Each is a definitional equality closed by the Agda type checker. At the interpretation level, one may compare these values with spacetime dimension, gauge-sector counts, spatial-to-temporal split, and the inverse fine-structure constant. The next chapter addresses the last formal question first: is the assignment of fields to these invariants itself unique, or could a second admissible representation survive the same graph? The canonicity of α^{-1} as a derived invariant—including the proof that no alternative degree-≤ 3 formula reaches 137—follows in §51.

Chapter 45

K_4 Representation Theory

The admissible physical representation of K_4 must be unique: otherwise the passage from graph invariants to physical quantities would reintroduce contingency. This chapter forces uniqueness by anchoring one field to the simplex cardinality and chaining every remaining field to previously fixed invariants until no representational freedom survives.

Structural infrastructure

The infrastructure isolates the raw objects on which representation theory acts: vertices, basis states, adjacency, and neighbor summation. Nothing interpretive happens here; the section fixes the combinatorial carrier that every later representation claim must respect.

```

The representation record

A physics representation that floats freely above its graph would reintroduce contingency at the worst possible moment: after every graph invariant has been locked down. The record below eliminates that risk by packaging 17 unknowns with exactly one anchor (dim $\equiv V$) and 16 directed chain constraints. Once the anchor connects to K_4, every remaining field is forced to exactly one value through a rigid directed chain: dim fixes n-spatial, which fixes n-temporal, which fixes every subsequent field.

Constraint: Every physical field must be uniquely determined by the K_4 anchor; no field may carry independent freedom.

Elimination: Any record with fewer than 17 fields fails to cover the invariant chain; any record with an anchor weaker than dim $\equiv$ vertexCountK4 leaves representational freedom alive. The only surviving structure packages 17 fields with 1 anchor (dim $\equiv$ vertexCountK4) and 16 chained equalities. Each equality pins one field to a formula in previously fixed fields.

Consequence: The record is rigid: any admissible inhabitant is fully determined by the anchor alone. This is proved in the sections that follow.

```

Existence: the canonical witness

A record type with constraints is vacuously consistent until an inhabitant is exhibited. Without a witness, the forcing chain is a theorem about nothing. Existence is witnessed by the canonical assignment obtained from the forced constants. Each proof closes by refl because the assigned values are not guesses; they are exactly the normal forms already determined by the constraint chain.

Constraint: The 17 fields and 16 chained equalities must be simultaneously satisfiable.

Elimination: Each field is assigned its forced value (4, 3, 1, 6, 4, 2, 137, ...) and every constraint proof closes by refl—no alternative assignment survives the chain.

Consequence: The representation is inhabited. Combined with uniqueness, this makes it a singleton.

Determination: the forcing chain resolves every field

Existence shows the record is inhabited. But an inhabited record with 17 fields could still harbour hidden freedom if some fields were underdetermined by the constraints. The forcing chain eliminates that possibility: for any admissible representation r, each field is compelled to a unique natural number by walking outward from the anchor.

For any admissible representation, each field is forced to a specific value. The argument walks outward from the anchor, eliminating one degree of freedom per constraint until the entire record is rigid.

Constraint: Every field of every admissible representation must evaluate to the same number; otherwise representational freedom survives.

Elimination: Start from dim $\equiv 4$ (the anchor). Each subsequent field is forced by eliminating every alternative: n-spatial $\equiv 3$ via cg-deg, then n-temporal $\equiv 1$ via cg-temporal, and so on through all 17 fields. No degree of freedom survives the chain.

Consequence: The representation is not just inhabited but rigid. Every field of every admissible representation evaluates to exactly one value.

Uniqueness: any two representations agree

Existence alone leaves a lethal gap: if two distinct representations of K_4 could coexist, the physical constants would depend on which representation was chosen, and no experiment could decide between them. Uniqueness closes that gap. Since ForcedValues pins every field of every admissible representation to the same normal form, any two representations must agree field by field. Singletonhood is therefore proved, not declared.

Constraint: Two admissible representations r_1, r_2 must agree on every field, or representational contingency survives.

Elimination: For each field, chain F_1.field-is-k with sym F_2.field-is-k to eliminate any divergence between r_1.field and r_2.field.

Consequence: The physics representation of K_4 is a singleton. No alternative survives.

Singleton: the representation has exactly one inhabitant

The preceding section proves that any two admissible representations agree on all 17 data fields. But data-field agreement is not yet record equality. The record K4PhysRep also carries 16 proof fields—each of type $n \equiv m$ for specific natural numbers. If two proofs of the same natural-number equation could differ, then two representations with identical data could still diverge on the proof layer, and the singleton claim would harbour invisible slack.

Under –without-K, uniqueness of identity proofs is not given for free. It must be derived. The route is Hedberg's theorem: any type with decidable equality satisfies UIP. Natural numbers have decidable equality by induction. Therefore every proof $p : m \equiv n$ on $\mathbb{N}$ is uniquely determined. Once the proof fields are locked, record eta forces full propositional equality.

Constraint: If two proofs of the same $\mathbb{N}$-equation could differ, the representation would fork at the proof layer even after the data layer is fixed.

Elimination: Decidable equality on $\mathbb{N}$ by mutual recursion eliminates undecidable cases. Hedberg's theorem extracts a constant endomorphism on identity proofs from the decision procedure, eliminating all non-canonical retracts. Corollary: $\mathbb{N}$-UIP—no two distinct proofs of the same equation survive. Record-level singleton: transport every data field of an arbitrary representation to its forced value using ForcedValues, apply $\mathbb{N}$-UIP to eliminate all proof-field divergence, close by record eta.

Consequence: The physics record of K_4 has propositionally exactly one inhabitant. The singleton is not 17 separate coincidences stitched together by convention. It is a single theorem: K4PhysRep-singleton.

Constraint derivation: from named invariants to canonical witness

Every K4PhysRep field is forced directly from named K_4 invariants. Bare numerals disappear from the assignment layer, and each proof closes by refl because the chain formulas are exactly the definitions of the named invariants they invoke.

```

Physical quantities as computable K_4 invariants

The remaining formal gap between graph invariants and the representation record is eliminated here. Each represented quantity is forced to be a computable function of K_4 data, so the internal identification is no longer rhetorical: the output of the graph computation is exactly the value carried by the representation chain. Whether a given represented quantity should also be read as a physical observable remains a separate interpretive question.

Representation Completeness

The record built below is already rigid once one enters it. But the stronger pressure comes from outside. If there were two admissible ways for physics to sit on the same K_4 invariant spine, then the constants would no longer be observables forced by structure; they would be artifacts of representational wording. That would collapse the claim at the final step. The graph would still survive, but the bridge into measurement would fork, and every numerical coincidence could be dismissed as notation. This fork must be shattered.

Constraint: Any admissible physical representation of K_4 must preserve the named invariant chain already fixed: vertex count, edge count, face count, Euler characteristic, spectral data, and the derived observables assembled from them. No representational wrapper may introduce additional degrees of freedom while claiming to describe the same structure.

Elimination: The present chapter eliminates every alternative inhabitant of $\mathrm{K4PhysRep}$, proving singletonhood. The external completeness theorem $\mathrm{RepresentationComplete}$ states: for any admissible K_4 representation r, every observable field agrees with the canonical record.

$$\mathrm{RepresentationComplete} : (\text{admissible representation of } K_4) \to (\text{canonical } K4PhysRep),$$

or equivalently, that every admissible representation is canonically isomorphic to the unique record assembled from the invariant basis.

Consequence: With the closure theorem $\mathrm{RepresentationComplete}$ proven, the formal bridge no longer says merely that one chosen representation works. It says that no rival admissible representation survives. Any later physical reading must therefore attach to a unique formal record rather than to a convenient encoding chosen after the fact.

Local graph observables

The first block isolates the vertex-local computations: row sums, propagation directions, and the basis witness showing that the local signal really is the degree. That keeps the local layer visible before the global quantities are assembled from it.

```
-- § Physical quantities as computable K₄ functions
module PhysicalQuantities where

-- § Signal directions: adjacency row sum at each vertex
signal-directions : K4Vertex → ℕ
signal-directions v =
 adjacent v v₀ + adjacent v v₁ + adjacent v v₂ + adjacent v v₃

-- § Signal is vertex-uniform and equals degree
signal-is-degree : (v : K4Vertex) → signal-directions v ≡ degree-K4
signal-is-degree = law-adjacency-degree

-- § Each signal propagates independently (basis property)
signal-independent : (u v : K4Vertex) →
 sum-neighbors (K4-basis u) v ≡ adjacent v u
signal-independent = law-basis-spreads
```

Global quantities built from the local layer

Once the local observables are fixed, the rest of the physics-facing quantities are short global computations. Splitting them into a second block mirrors the earlier chapters, where constructors come first and packaged consequences follow afterward.

```
-- § Boundary quanta: 2-simplex count = face count

interaction-channels = edgeCountK4
```

Observable representation and closure

The representation is rebuilt entirely from computed observables. This removes the last appearance of ad hoc assignment: every field is a graph-theoretic computation on K_4, and every constraint reduces to refl because the defining formula already is the required computation.

```
-- § K4PhysRep from computed quantities (no bare numerals)

; ph-baryon-den = refl
}

-- § Closure: observable-rep IS canonical-rep (definitional equality)
observable-is-canonical : observable-rep ≡ canonical-rep
observable-is-canonical = refl
```

The observable principle

The observable principle removes the final semantic slack: an observable on K_4 is exactly an automorphism-invariant computable function. Because K_4 is vertex-transitive, every local observable must be uniform across vertices, while every global observable is already fixed by graph-isomorphism invariance on the named combinatorial data.

Observable types and invariance

```
-- § K4 vertex-level invariance
IsK4Invariant : (K4Vertex → ℕ) → Set
IsK4Invariant f = (v w : K4Vertex) → f v ≡ f w

-- § Local observable: vertex function + uniformity proof
LocalObservable : Set
LocalObservable = Σ (K4Vertex → ℕ) IsK4Invariant

-- § Global admissible observables collapse to four canonical codes.
data GlobalObservable : Set where
 go-boundary go-correlator go-observer go-channels : GlobalObservable

eval-global-observable : GlobalObservable → ℕ
eval-global-observable go-boundary = boundary-quanta
eval-global-observable go-correlator = max-sq-correlator
```

```
eval-global-observable go-observer   = observer-directions
eval-global-observable go-channels   = interaction-channels

-- § Complete observable type
Observable : Set
Observable = LocalObservable ⊎ GlobalObservable

-- § Every invariant function has a unique value, independent of vertex
invariant-value : (f : K4Vertex → ℕ) → IsK4Invariant f → ℕ
invariant-value f _ = f v₀

invariant-any-vertex : (f : K4Vertex → ℕ) → (inv : IsK4Invariant f) →
 (v : K4Vertex) → f v ≡ invariant-value f inv
invariant-any-vertex f inv v = inv v v₀

observable-value : Observable → ℕ
observable-value (inj₁ (f , inv)) = invariant-value f inv
observable-value (inj₂ g) = eval-global-observable g
```

Local observable witnesses

The next block shows the local pattern once: define the observable, prove vertex-uniformity, then read off its canonical value. Keeping that pattern separate prevents the proof witness from disappearing inside the later list of global observables.

```
-- § Signal-directions is a local observable
signal-invariant : IsK4Invariant signal-directions
signal-invariant v w =
 trans (signal-is-degree v) (sym (signal-is-degree w))

signal-observable : LocalObservable
signal-observable = signal-directions , signal-invariant

-- § Observed value is degree = 3
signal-observed-value : invariant-value signal-directions signal-invariant
                        ≡ degree-K4
signal-observed-value = refl

-- § Adjacency row sum is a local observable
adj-row : K4Vertex → K4Vertex → ℕ
adj-row v w = adjacent v w

adj-row-sum-invariant : IsK4Invariant (λ v →
 adj-row v v₀ + adj-row v v₁ + adj-row v v₂ + adj-row v v₃)
adj-row-sum-invariant v w =
 trans (law-adjacency-degree v) (sym (law-adjacency-degree w))
```

Global observable witnesses

The global layer can no longer remain an unrestricted numeric container. If every natural number counted as a global observable merely because it was written down after the graph was fixed, descriptive freedom would return through naming. The admissibility filter therefore has

to close the space itself. Only four primitive global classes survive: boundary, correlator, observer, and channels. Everything else in the later physics discussion is either a value of this basis or a derived ledger invariant, not a fifth admissible global observable.

Constraint: A global observable must be presentation-independent and forced by the invariant spine of K_4. If the global layer were identified with arbitrary naturals, the observable principle would fail exactly where it is supposed to become strongest.

Elimination: Any global sector wider than a finite four-code basis is eliminated by the presentation-independence and automorphism-invariance constraints. The surviving admissible sector is represented by exactly four codes, together with a canonical evaluation map into the already forced graph quantities.

Consequence: Global admissibility is an elimination statement rather than a naming convention. The space of primitive global observables is closed, finite, and exhausted by the four surviving codes.

Chapter 46

K_4 Vertex Permutations

The automorphism group $\mathrm{Aut}(K_4) \cong S_4$ acts on the four vertices by permutation. For a complete graph, every bijection is a graph automorphism—adjacency depends only on distinctness, and bijections preserve distinctness. The group acts 2-transitively: for any two ordered pairs of distinct vertices, some permutation maps one to the other.

This chapter builds the formal infrastructure. The strategy re-uses the permutation machinery already proven for EndoCase—transpositions, involutivity, transitivity—by lifting it through an explicit bijection K4Vertex ↔ EndoCase. No case table is re-proved; the 64-entry involution table for swapEndo does all the work.

Constraint: The permutation group must act on K4Vertex with full bijectivity proofs, not merely produce functions.

Elimination: Any permutation structure that lacks full bijectivity proofs is eliminated by the round-trip requirement. The only surviving form is a record K4Perm packaging transport and inverse with round-trip laws. Transpositions and compositions inherit these from EndoPerm. Decidable equality on K4Vertex provides the case analysis that the adjacency-preservation proof requires.

Consequence: Any ℕ-valued function on vertex pairs that is invariant under all K4Perm has a single uniform value on all off-diagonal entries. This is the core tool the forced-propagation elimination will use.

Vertex bijection

The bijection between K4Vertex and EndoCase maps constructors to constructors and round-trips in both directions.

```
k4-to-endo : K4Vertex → EndoCase
k4-to-endo v₀ = case-constL
k4-to-endo v₁ = case-constR
k4-to-endo v₂ = case-id
k4-to-endo v₃ = case-dual

endo-to-k4 : EndoCase → K4Vertex
endo-to-k4 case-constL = v₀
```

```
endo-to-k4 case-constR = v₁
endo-to-k4 case-id     = v₂
endo-to-k4 case-dual = v₃

k4-endo-k4 : (v : K4Vertex) → endo-to-k4 (k4-to-endo v) ≡ v
k4-endo-k4 v₀ = refl
k4-endo-k4 v₁ = refl
k4-endo-k4 v₂ = refl
k4-endo-k4 v₃ = refl

endo-k4-endo : (e : EndoCase) → k4-to-endo (endo-to-k4 e) ≡ e
endo-k4-endo case-constL = refl
endo-k4-endo case-constR = refl
endo-k4-endo case-id     = refl
endo-k4-endo case-dual = refl
```

Permutation record and lifting

A K4Perm is a bijection on K4Vertex: forward and inverse maps with round-trip proofs. The function liftPerm converts any EndoPerm into a K4Perm by conjugating through the vertex bijection.

```
record K4Perm : Set where
 field
  k4to     : K4Vertex → K4Vertex
  k4from : K4Vertex → K4Vertex
  k4-to-from : (v : K4Vertex) → k4to (k4from v) ≡ v
  k4-from-to : (v : K4Vertex) → k4from (k4to v) ≡ v

open K4Perm public

liftPerm : EndoPerm → K4Perm
liftPerm σ = record
 { k4to     = λ v → endo-to-k4 (eto σ (k4-to-endo v))
 ; k4from = λ v → endo-to-k4 (efrom σ (k4-to-endo v))
 ; k4-to-from = λ v →
   trans (cong (λ e → endo-to-k4 (eto σ e))
                 (endo-k4-endo (efrom σ (k4-to-endo v))))
         (trans (cong endo-to-k4 (eto-efrom σ (k4-to-endo v)))
                 (k4-endo-k4 v))
 ; k4-from-to = λ v →
   trans (cong (λ e → endo-to-k4 (efrom σ e))
                 (endo-k4-endo (eto σ (k4-to-endo v))))
         (trans (cong endo-to-k4 (efrom-eto σ (k4-to-endo v)))
                 (k4-endo-k4 v))
 }
```

Composition of two permutations inherits bijectivity from the components.

```
k4Perm-comp : K4Perm → K4Perm → K4Perm
k4Perm-comp σ τ = record
 { k4to     = λ v → k4to σ (k4to τ v)
 ; k4from = λ v → k4from τ (k4from σ v)
 ; k4-to-from = λ v →
   trans (cong (k4to σ) (k4-to-from τ (k4from σ v)))
         (k4-to-from σ v)
 ; k4-from-to = λ v →
   trans (cong (k4from τ) (k4-from-to σ (k4to τ v)))
         (k4-from-to τ v)
 }
```

Decidable equality and adjacency lemmas

Decidable equality on K4Vertex enables proofs that branch on whether two vertices coincide. It is forced by constructor discrimination: the four constructors are pairwise distinguishable.

```
K4-decEq : (v w : K4Vertex) → (v ≡ w) ⊎ (v ≢ w)
K4-decEq v₀ v₀ = inj₁ refl
K4-decEq v₁ v₁ = inj₁ refl
K4-decEq v₂ v₂ = inj₁ refl
K4-decEq v₃ v₃ = inj₁ refl
K4-decEq v₀ v₁ = inj₂ (λ ())
K4-decEq v₀ v₂ = inj₂ (λ ())
K4-decEq v₀ v₃ = inj₂ (λ ())
K4-decEq v₁ v₀ = inj₂ (λ ())
K4-decEq v₁ v₂ = inj₂ (λ ())
K4-decEq v₁ v₃ = inj₂ (λ ())
K4-decEq v₂ v₀ = inj₂ (λ ())
K4-decEq v₂ v₁ = inj₂ (λ ())
K4-decEq v₂ v₃ = inj₂ (λ ())
K4-decEq v₃ v₀ = inj₂ (λ ())
K4-decEq v₃ v₁ = inj₂ (λ ())
K4-decEq v₃ v₂ = inj₂ (λ ())
```

Two structural facts about adjacent: it returns 0 on the diagonal and 1 on every off-diagonal pair. Together they say that adjacency in K_4 is exactly distinctness.

```
adj-self : (v : K4Vertex) → adjacent v v ≡ 0
adj-self v₀ = refl
adj-self v₁ = refl
adj-self v₂ = refl
adj-self v₃ = refl

K4-distinct-adj : (v w : K4Vertex) → v ≢ w → adjacent v w ≡ 1
K4-distinct-adj v₀ v₀ ne = ⊥-elim (ne refl)
K4-distinct-adj v₀ v₁ _ = refl
K4-distinct-adj v₀ v₂ _ = refl
K4-distinct-adj v₀ v₃ _ = refl
K4-distinct-adj v₁ v₀ _ = refl
K4-distinct-adj v₁ v₁ ne = ⊥-elim (ne refl)
K4-distinct-adj v₁ v₂ _ = refl
K4-distinct-adj v₁ v₃ _ = refl
K4-distinct-adj v₂ v₀ _ = refl
K4-distinct-adj v₂ v₁ _ = refl
K4-distinct-adj v₂ v₂ ne = ⊥-elim (ne refl)
K4-distinct-adj v₂ v₃ _ = refl
K4-distinct-adj v₃ v₀ _ = refl
K4-distinct-adj v₃ v₁ _ = refl
K4-distinct-adj v₃ v₂ _ = refl
K4-distinct-adj v₃ v₃ ne = ⊥-elim (ne refl)
```

Injectivity of any K4Perm follows from the round-trip law: compose with the inverse on both sides.

```
k4-injective : (σ : K4Perm) → (v w : K4Vertex) →
 k4to σ v ≡ k4to σ w → v ≡ w
k4-injective σ v w p =
 trans (sym (k4-from-to σ v))
       (trans (cong (k4from σ) p)
              (k4-from-to σ w))
```

Transitivity and 2-transitivity

The group acts 1-transitively: any vertex can be sent to any other by some permutation. The proof lifts endoPerm-send through the bijection.

```
k4Perm-send : (a a' : K4Vertex) → Σ K4Perm (λ σ → k4to σ a ≡ a')
k4Perm-send a a' =
 let ep = endoPerm-send (k4-to-endo a) (k4-to-endo a')
 in (liftPerm (fst ep) ,
    trans (cong endo-to-k4 (snd ep)) (k4-endo-k4 a'))
```

2-transitivity is the key tool for the propagation elimination: for any two ordered pairs of distinct vertices, some permutation maps one to the other. The reference pair is (v_0, v_1). Each of the 12 off-diagonal targets is reached by at most two transpositions. Every case reduces by computation to refl.

```
edge-map : (v w : K4Vertex) → v ≠ w →

                                (liftPerm (permSwap case-constR case-id))
                   , (refl , refl))
edge-map v₃ v₃ ne = ⊥-elim (ne refl)
```

Adjacency preservation

In K_4—and only in a complete graph—every bijection is a graph automorphism. The proof does not inspect the permutation: it branches on whether the two vertices coincide. On the diagonal, both sides equal 0; off-diagonal, injectivity forces both sides to 1.

```
k4-perm-preserves-adj : (σ : K4Perm) → (v w : K4Vertex) →
 adjacent v w ≡ adjacent (k4to σ v) (k4to σ w)
k4-perm-preserves-adj σ v w with K4-decEq v w
... | inj₁ refl = trans (adj-self v) (sym (adj-self (k4to σ v)))
... | inj₂ ne = trans (K4-distinct-adj v w ne)
                      (sym (K4-distinct-adj (k4to σ v) (k4to σ w)
                            (λ p → ne (k4-injective σ v w p))))
```

K4-invariance and uniform edge weight

A numeric function on vertex pairs is K_4-invariant when its value is preserved under every permutation.

```
IsK4PermInvariant : (K4Vertex → K4Vertex → ℕ) → Set
IsK4PermInvariant f = (σ : K4Perm) → (v w : K4Vertex) →
 f v w ≡ f (k4to σ v) (k4to σ w)
```

The central consequence: any K_4-invariant function assigns the same value to every pair of distinct vertices. The proof picks two permutations—one from edge-map for each target pair—and chains the invariance equalities through the common reference value $f\, v_0\, v_1$.

```
invariant-uniform-edges : (f : K4Vertex → K4Vertex → ℕ) →
 IsK4PermInvariant f →
 (v w v' w' : K4Vertex) → v ≢ w → v' ≢ w' → f v w ≡ f v' w'
invariant-uniform-edges f inv v w v' w' ne ne' =
 trans (sym (to-ref v w ne)) (to-ref v' w' ne')
 where
  to-ref : (a b : K4Vertex) → a ≢ b → f v₀ v₁ ≡ f a b
  to-ref a b ne-ab =
   let em = edge-map a b ne-ab
       σ = fst em
       p = fst (snd em)
       q = snd (snd em)
   in trans (inv σ v₀ v₁)
            (trans (cong (λ x → f x (k4to σ v₁)) p)
                   (cong (f a) q))
```

This is the exact place where the admissibility architecture must sit. The permutation chapter supplies the transport engine: a single reference value on one edge, face, or vertex is moved across the full orbit of the same simplicial dimension. The three physics-constant chapters therefore no longer need to postulate pointwise lower and upper bounds on every simplex. It is enough to bracket one reference simplex and combine that bracket with invariance and the local diagonal law. The next three chapters apply that same pattern in dimensions 1, 2, and 0 respectively.

Chapter 47

Forced Propagation

The arithmetic identity $\text{max-propagation-per-edge} \equiv 1$ was proved earlier by reduction. That identity computes the right number but does not eliminate alternatives: it never defines what a propagation law *is*, so it never shows that rival laws fail.

This chapter closes that gap. A propagation law is any numeric function on vertex pairs, subject to four independent structural constraints—each of which admits genuine alternatives on its own. Only their intersection is a singleton. The elimination is not a case split. It is a sandwich argument: automorphism invariance collapses the off-diagonal entries to a single value r, the lower bound forces $1 \leq r$, the upper bound forces $r \leq 1$, and antisymmetry closes to $r = 1$.

Constraint: The candidate space is deliberately wide: *any* function $K_4\text{Vertex} \to K_4\text{Vertex} \to \mathbb{N}$. Candidates such as $P \equiv 2$ on all edges, or $P \equiv 3$ on one edge and 1 elsewhere, are included and must be eliminated by the filter, not excluded by the definition.

Elimination: Four filters are applied in sequence:

1. *Locality* — zero on the diagonal.

2. *Edge support* — every off-diagonal entry is at least 1.

3. K_4*-invariance* — the law is preserved under every vertex permutation.

4. *Boundedness* — every entry is at most 1.

Filters 2 and 4 are the wide brackets; filter 3 does the structural work. After invariance, the 12 off-diagonal values collapse to a single unknown $r = P\, v_0\, v_1$. Edge support gives $1 \leq r$; boundedness gives $r \leq 1$; antisymmetry of $\leq$ yields $r \equiv 1$. The diagonal is 0 by locality. Together: $P \equiv \text{adjacent}$.

Consequence: The propagation rate is forced without enumerating vertex pairs. The earlier arithmetic computation becomes a corollary of a structural elimination.

Propagation candidates

A propagation law assigns a natural-number weight to each ordered vertex pair. No constraint is placed yet—the type is deliberately wide. The constant-2 law, the constant-7 law, and every non-uniform variant are all members of this type.

```
PropagationLaw : Set
PropagationLaw = K4Vertex → K4Vertex → ℕ
```

The four admissibility filters

Locality demands zero weight on the diagonal: a vertex does not propagate to itself.

```
IsLocal : PropagationLaw → Set
IsLocal P = (v : K4Vertex) → P v v ≡ 0
```

Edge support demands that every off-diagonal pair carries weight at least 1. This is deliberately weak—it admits $P = 2$, $P = 5$, any non-zero value.

```
HasEdgeSupport : PropagationLaw → Set
HasEdgeSupport P = (v w : K4Vertex) → v ≢ w → 1 ≤ P v w

ReferenceEdgeLower : PropagationLaw → Set
ReferenceEdgeLower P = 1 ≤ P v₀ v₁
```

Boundedness demands that no single edge carries weight above 1. Physically: propagation is local, with at most one unit of signal per direct link. No shortcutting, no amplification. This is the upper bracket that meets the lower bracket from edge support.

```
IsBounded : PropagationLaw → Set
IsBounded P = (v w : K4Vertex) → P v w ≤ 1

ReferenceEdgeUpper : PropagationLaw → Set
ReferenceEdgeUpper P = P v₀ v₁ ≤ 1
```

K_4-invariance demands that the law is preserved under every vertex permutation. This is the structural filter that, in the previous chapter, was shown to collapse all off-diagonal entries to a single value.

The full admissibility record packages all four constraints. Each constraint admits genuine alternatives on its own; only their intersection is a singleton.

```
record AdmissiblePropagation (P : PropagationLaw) : Set where
 field
  local : IsLocal P
  invariant : IsK4PermInvariant P
  ref-lower : ReferenceEdgeLower P
  ref-upper : ReferenceEdgeUpper P
```

The elimination

The elimination proceeds without enumerating vertex pairs. It uses three lemmas, each of which is structural rather than computational.

Step 1: Invariance collapses off-diagonal to one value. By invariant-uniform-edges (proved in the previous chapter), any K_4-invariant function assigns the same value r to every pair of distinct vertices. The reference value is $P\, v_0\, v_1$.

```
propagation-uniform : (P : PropagationLaw) → IsK4PermInvariant P →
 (v w : K4Vertex) → v ≠ w → P v w ≡ P v₀ v₁
propagation-uniform P inv v w ne =
 invariant-uniform-edges P inv v w v₀ v₁ ne (λ ())
```

Step 2: Invariance transports the brackets. The lower and upper brackets are imposed only on the reference edge (v_0, v_1). Invariance transports them to every off-diagonal edge.

```
propagation-supported : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → v ≠ w → 1 ≤ P v w
propagation-supported P adm v w ne =
 subst (λ n → 1 ≤ n)
  (sym (propagation-uniform P (AdmissiblePropagation.invariant adm) v w ne))
  (AdmissiblePropagation.ref-lower adm)

propagation-bounded : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → P v w ≤ 1
propagation-bounded P adm v w with K4-decEq v w
... | inj₁ refl = subst (λ n → n ≤ 1) (sym (AdmissiblePropagation.local adm v)) z≤n
... | inj₂ ne = subst (λ n → n ≤ 1)
                (sym (propagation-uniform P (AdmissiblePropagation.invariant adm) v w ne))
                (AdmissiblePropagation.ref-upper adm)
```

Step 3: The sandwich. The transported lower bound gives $1 \leq r$. The transported upper bound gives $r \leq 1$. Antisymmetry of $\leq$ closes to $r \equiv 1$.

```
v₀≠v₁ : v₀ ≠ v₁
v₀≠v₁ ()

propagation-edge-value : (P : PropagationLaw) → AdmissiblePropagation P →
 P v₀ v₁ ≡ 1
propagation-edge-value P adm =
 ≤-antisym
  (AdmissiblePropagation.ref-upper adm)
  (AdmissiblePropagation.ref-lower adm)
```

Step 4: Assembly. Every off-diagonal entry equals 1; every diagonal entry equals 0. Both agree with adjacent, whose definition is exactly 0 on the diagonal and 1 elsewhere.

```
propagation-off-diag : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → v ≠ w → P v w ≡ 1
propagation-off-diag P adm v w ne =
 trans (propagation-uniform P (AdmissiblePropagation.invariant adm) v w ne)
       (propagation-edge-value P adm)

propagation-forced : (P : PropagationLaw) → AdmissiblePropagation P →
 (v w : K4Vertex) → P v w ≡ adjacent v w
propagation-forced P adm v w with K4-decEq v w
... | inj₁ refl = trans (AdmissiblePropagation.local adm v)
                        (sym (adj-self v))
```

```
... | inj₂ ne = trans (propagation-off-diag P adm v w ne)
                     (sym (K4-distinct-adj v w ne))
```

The core theorem now branches on a single binary question—same vertex or different?—not on 16 constructor pairs. The structural work is done by invariance; the arithmetic is done by the sandwich.

Existence

The adjacency matrix itself is admissible: it satisfies all four constraints. Locality and boundedness hold by computation. Edge support follows from K4-distinct-adj. Invariance follows from k4-perm-preserves-adj.

```
adjacent-is-local : IsLocal adjacent
adjacent-is-local v₀ = refl
adjacent-is-local v₁ = refl
adjacent-is-local v₂ = refl
adjacent-is-local v₃ = refl

adjacent-supported : HasEdgeSupport adjacent
adjacent-supported v w ne = subst (λ n → 1 ≤ n)
 (sym (K4-distinct-adj v w ne)) (s≤s z≤n)

adjacent-bounded : IsBounded adjacent
adjacent-bounded v₀ v₀ = z≤n
adjacent-bounded v₀ v₁ = s≤s z≤n
adjacent-bounded v₀ v₂ = s≤s z≤n
adjacent-bounded v₀ v₃ = s≤s z≤n
adjacent-bounded v₁ v₀ = s≤s z≤n
adjacent-bounded v₁ v₁ = z≤n
adjacent-bounded v₁ v₂ = s≤s z≤n
adjacent-bounded v₁ v₃ = s≤s z≤n
adjacent-bounded v₂ v₀ = s≤s z≤n
adjacent-bounded v₂ v₁ = s≤s z≤n
adjacent-bounded v₂ v₂ = z≤n
adjacent-bounded v₂ v₃ = s≤s z≤n
adjacent-bounded v₃ v₀ = s≤s z≤n
adjacent-bounded v₃ v₁ = s≤s z≤n
adjacent-bounded v₃ v₂ = s≤s z≤n
adjacent-bounded v₃ v₃ = z≤n

adjacent-invariant : IsK4PermInvariant adjacent
adjacent-invariant σ v w = k4-perm-preserves-adj σ v w

adjacent-ref-lower : ReferenceEdgeLower adjacent
adjacent-ref-lower = s≤s z≤n

adjacent-ref-upper : ReferenceEdgeUpper adjacent
adjacent-ref-upper = s≤s z≤n

adjacent-admissible : AdmissiblePropagation adjacent
adjacent-admissible = record
 { local = adjacent-is-local
 ; invariant = adjacent-invariant
 ; ref-lower = adjacent-ref-lower
 ; ref-upper = adjacent-ref-upper
 }
```

Summary and the discrete speed of light

The full result: the admissible propagation law exists, is unique, and has effective rate 1. The uniqueness is structural—invariance, sandwich, antisymmetry—not a 4×4 case table.

```
record ForcedPropagationResult : Set where
 field
  witness  : AdmissiblePropagation adjacent
  unique   : (P : PropagationLaw) → AdmissiblePropagation P →
             (v w : K4Vertex) → P v w ≡ adjacent v w
  rate-is-1 : (P : PropagationLaw) → AdmissiblePropagation P →
             (v w : K4Vertex) → adjacent v w ≡ 1 → P v w ≡ 1

theorem-forced-propagation : ForcedPropagationResult
theorem-forced-propagation = record
 { witness = adjacent-admissible
 ; unique  = propagation-forced
 ; rate-is-1 = λ P adm v w hw → trans (propagation-forced P adm v w) hw
 }
```

With the elimination closed, the propagation rate can be named for what it is: the unit propagation speed in native FD units. The value $c_{\mathrm{FD}} = 1$ is not a numerical input or a convenient convention. It is the only value that survives the four-filter admissibility test.

```
c-FD : ℕ
c-FD = 1

c-FD-is-propagation-rate : c-FD ≡ max-propagation-per-edge
c-FD-is-propagation-rate = refl
```

Chapter 48

Forced Minimal Action

K_4 has a forced cycle structure. At the tetrahedral level there are exactly four triangular faces, one opposite each vertex, and these are the minimal non-trivial closed simplicial loops of the graph. An action law assigns a natural-number weight to each face. The elimination now uses the same symmetry logic as the propagation chapter: automorphism-invariance under $\mathrm{Aut}(K_4)$ collapses all four faces to one global value, and minimality pins that value at 1.

Constraint: The candidate space must not encode the target value. An action law is any function from triangles to $\mathbb{N}$, and the constraints are external filters.

Elimination: Four filters are applied:

1. *Non-triviality* — every face has positive weight.
2. K_4*-invariance* — the law is preserved under every vertex permutation.
3. *Lower bound* — every face carries weight at least 1.
4. *Minimality* — no face carries weight above 1.

Filters 3 and 4 are the wide brackets; filter 2 does the structural work. After invariance, the four face values collapse to a single unknown $r = A\,\mathit{tri}\text{-}012$. The lower bound gives $1 \leq r$; minimality gives $r \leq 1$; antisymmetry of $\leq$ yields $r \equiv 1$.

Consequence: The discrete action unit $\hbar_{\mathrm{FD}} = 1$ is forced by a sandwich argument parallel to propagation. The earlier arithmetic statement $\mathrm{triangle\text{-}loop\text{-}order} = 1$ becomes a corollary.

Triangles and action candidates

A triangle face of the tetrahedral K_4 is determined by the unique vertex it omits. There are therefore exactly four such faces, one opposite each vertex. This representation is the right one for automorphism-invariance: a vertex permutation acts on faces simply by acting on the omitted vertex.

```
K4Triangle : Set
K4Triangle = K4Vertex
```

```
triangle-map : K4Perm → K4Triangle → K4Triangle
triangle-map σ t = k4to σ t
```

An action law assigns a natural-number weight to each triangle. No constraint is assumed yet.

```
ActionLaw : Set
ActionLaw = K4Triangle → ℕ

tri-012 : K4Triangle
tri-012 = v₃

tri-013 : K4Triangle
tri-013 = v₂

tri-023 : K4Triangle
tri-023 = v₁

tri-123 : K4Triangle
tri-123 = v₀
```

The four admissibility conditions mirror the propagation chapter: non-triviality, automorphism-invariance, a lower bound, and a minimality upper bound. Each filter admits genuine alternatives on its own; only their intersection is a singleton.

```
IsNonTrivial : ActionLaw → Set
IsNonTrivial A = (t : K4Triangle) → A t ≡ 0 → ⊥

IsActionInvariant : ActionLaw → Set
IsActionInvariant A = (σ : K4Perm) → (t : K4Triangle) →
 A t ≡ A (triangle-map σ t)

ActionBound : ActionLaw → Set
ActionBound A = (t : K4Triangle) → 1 ≤ A t

ReferenceTriangleLower : ActionLaw → Set
ReferenceTriangleLower A = 1 ≤ A tri-012

IsMinimal : ActionLaw → Set
IsMinimal A = (t : K4Triangle) → A t ≤ 1

ReferenceTriangleUpper : ActionLaw → Set
ReferenceTriangleUpper A = A tri-012 ≤ 1

record AdmissibleAction (A : ActionLaw) : Set where
 field
  invariant : IsActionInvariant A
  ref-lower : ReferenceTriangleLower A
  ref-upper : ReferenceTriangleUpper A
```

The four canonical triangle faces of K_4 are the faces opposite v_3, v_2, v_1, and v_0 respectively.

Existence: the unit action law

The constant-1 action law is admissible: it is trivially invariant, its value is never zero, every triangle satisfies $1 \leq 1$, and no triangle exceeds 1.

```
unit-action : ActionLaw
unit-action _ = 1

unit-action-invariant : IsActionInvariant unit-action
unit-action-invariant _ _ = refl

unit-action-bounded : ActionBound unit-action
unit-action-bounded _ = s≤s z≤n

unit-action-minimal : IsMinimal unit-action
unit-action-minimal _ = s≤s z≤n

unit-action-ref-lower : ReferenceTriangleLower unit-action
unit-action-ref-lower = s≤s z≤n

unit-action-ref-upper : ReferenceTriangleUpper unit-action
unit-action-ref-upper = s≤s z≤n

unit-action-admissible : AdmissibleAction unit-action
unit-action-admissible = record
 { invariant = unit-action-invariant
 ; ref-lower = unit-action-ref-lower
 ; ref-upper = unit-action-ref-upper
 }
```

Elimination: invariance collapses to a single value

Automorphism-invariance forces every admissible action law to a single global value: all four faces lie in one orbit.

```
action-from-012 : (A : ActionLaw) → AdmissibleAction A →
 (t : K4Triangle) → A tri-012 ≡ A t
action-from-012 A adm t =
 let st = k4Perm-send tri-012 t in
 let σ = fst st in
 let p = snd st in
 trans (AdmissibleAction.invariant adm σ tri-012)
       (cong A p)

action-all-equal-to-012 : (A : ActionLaw) → AdmissibleAction A →
 (t : K4Triangle) → A t ≡ A tri-012
action-all-equal-to-012 A adm t =
 sym (action-from-012 A adm t)

action-global-value : (A : ActionLaw) → AdmissibleAction A →
 (t₁ t₂ : K4Triangle) → A t₁ ≡ A t₂
action-global-value A adm t₁ t₂ =
 trans (action-all-equal-to-012 A adm t₁)
       (action-from-012 A adm t₂)
```

Step 2: Invariance transports the brackets. The lower and upper brackets are imposed only on the reference face *tri*-012. Invariance transports them to every triangle.

```
action-bound : (A : ActionLaw) → AdmissibleAction A → ActionBound A
action-bound A adm t =
 subst (λ n → 1 ≤ n)
```

```
  (action-from-012 A adm t)
  (AdmissibleAction.ref-lower adm)

action-minimal : (A : ActionLaw) → AdmissibleAction A → IsMinimal A
action-minimal A adm t =
 subst (λ n → n ≤ 1)
  (action-from-012 A adm t)
  (AdmissibleAction.ref-upper adm)

action-nontrivial : (A : ActionLaw) → AdmissibleAction A → IsNonTrivial A
action-nontrivial A adm t eq =
 suc≤-impossible zero (subst (λ n → 1 ≤ n) eq (action-bound A adm t))
```

Step 3: The sandwich. The lower bound gives $1 \leq A\ tri\text{-}012$. The upper bound gives $A\ tri\text{-}012 \leq 1$. Antisymmetry closes to $A\ tri\text{-}012 \equiv 1$.

```
action-ref-value : (A : ActionLaw) → AdmissibleAction A → A tri-012 ≡ 1
action-ref-value A adm =
 ≤-antisym (AdmissibleAction.ref-upper adm)
           (AdmissibleAction.ref-lower adm)
```

Step 4: Assembly. Every face equals 1: invariance collapses to the reference value, the sandwich pins that value.

```
action-forced : (A : ActionLaw) → AdmissibleAction A →
 (t : K4Triangle) → A t ≡ 1
action-forced A adm t =
 trans (action-all-equal-to-012 A adm t)
       (action-ref-value A adm)
```

The core theorem branches on no cases at all. The structural work is done by invariance; the arithmetic is done by the sandwich—exactly as in the propagation chapter.

The summary record packages existence, unconditional uniqueness, and the global value.

```
record ForcedActionResult : Set where
 field
  witness  : AdmissibleAction unit-action
  global-value : (A : ActionLaw) → AdmissibleAction A →
                 (t₁ t₂ : K4Triangle) → A t₁ ≡ A t₂
  unique   : (A : ActionLaw) → AdmissibleAction A →
                 (t : K4Triangle) → A t ≡ 1

theorem-forced-action : ForcedActionResult
theorem-forced-action = record
 { witness = unit-action-admissible
 ; global-value = action-global-value
 ; unique  = action-forced
 }
```

The discrete action unit

The discrete action unit $\hbar_{\mathrm{FD}} = 1$ names the unique admissible action value in native FD units. The value is not merely minimal—it is the only survivor of the four-filter elimination. It is consistent with the triangle loop order already computed.

```
hbar-FD : ℕ
hbar-FD = 1

hbar-FD-is-loop-order : hbar-FD ≡ triangle-loop-order
hbar-FD-is-loop-order = refl
```

Chapter 49

Forced Geometric Coupling

The three forced constants of the FD system live on three simplicial dimensions of K_4:

$$\begin{array}{lll} \text{dim } 1 & \text{(edges)} & \longrightarrow c \\ \text{dim } 2 & \text{(faces)} & \longrightarrow \hbar \\ \text{dim } 0 & \text{(vertices)} & \longrightarrow G \end{array}$$

Propagation assigns a weight to each edge; the action assigns a weight to each face. Both were eliminated by the same four-filter sandwich. The gravitational coupling completes the triple: it assigns a curvature weight to each *vertex*—the 0-simplices where, in discrete geometry, curvature concentrates.

A curvature law is any function $K_4\text{Vertex} \to \mathbb{N}$, subject to four constraints—each of which admits genuine alternatives on its own:

1. *Non-triviality* — every vertex carries positive curvature.

2. K_4*-invariance* — the law is preserved under every vertex permutation.

3. *Lower bound* — every vertex carries curvature at least 1.

4. *Minimality* — no vertex carries curvature above 1.

The sandwich argument is identical to propagation and action: invariance collapses all four vertex values to a single unknown r, the lower bound gives $1 \leq r$, minimality gives $r \leq 1$, antisymmetry of $\leq$ yields $r \equiv 1$.

Constraint: The candidate space is deliberately wide: *any* function $K_4\text{Vertex} \to \mathbb{N}$. The constant-2 law, the constant-5 law, and any non-uniform variant are all members. The filters are external.

Elimination: Four filters applied in sequence collapse the space to a singleton.

Consequence: The discrete gravitational coupling $G_{\text{FD}} = 1$ is forced by the same simplicial elimination that forces c and $\hbar$. All three constants arise from the same architecture applied to three simplicial dimensions.

Curvature candidates

A curvature law assigns a natural-number weight to each vertex of K_4. No constraint is placed yet—the type is deliberately wide.

```
CurvatureLaw : Set
CurvatureLaw = K4Vertex → ℕ
```

The four admissibility conditions mirror the propagation and action chapters exactly.

```
IsCurvatureNonTrivial : CurvatureLaw → Set
IsCurvatureNonTrivial C = (v : K4Vertex) → C v ≡ 0 → ⊥

IsCurvatureInvariant : CurvatureLaw → Set
IsCurvatureInvariant C = (σ : K4Perm) → (v : K4Vertex) →
 C v ≡ C (k4to σ v)

CurvatureBound : CurvatureLaw → Set
CurvatureBound C = (v : K4Vertex) → 1 ≤ C v

ReferenceVertexLower : CurvatureLaw → Set
ReferenceVertexLower C = 1 ≤ C v₀

IsCurvatureMinimal : CurvatureLaw → Set
IsCurvatureMinimal C = (v : K4Vertex) → C v ≤ 1

ReferenceVertexUpper : CurvatureLaw → Set
ReferenceVertexUpper C = C v₀ ≤ 1

record AdmissibleCurvature (C : CurvatureLaw) : Set where
 field
  invariant : IsCurvatureInvariant C
  ref-lower : ReferenceVertexLower C
  ref-upper : ReferenceVertexUpper C
```

Existence: the unit curvature law

The constant-1 curvature law is admissible: it is trivially invariant, its value is never zero, every vertex satisfies $1 \leq 1$, and no vertex exceeds 1.

```
unit-curvature : CurvatureLaw
unit-curvature _ = 1

unit-curvature-invariant : IsCurvatureInvariant unit-curvature
unit-curvature-invariant _ _ = refl

unit-curvature-bounded : CurvatureBound unit-curvature
unit-curvature-bounded _ = s≤s z≤n

unit-curvature-minimal : IsCurvatureMinimal unit-curvature
unit-curvature-minimal _ = s≤s z≤n

unit-curvature-ref-lower : ReferenceVertexLower unit-curvature
unit-curvature-ref-lower = s≤s z≤n

unit-curvature-ref-upper : ReferenceVertexUpper unit-curvature
unit-curvature-ref-upper = s≤s z≤n

unit-curvature-admissible : AdmissibleCurvature unit-curvature
unit-curvature-admissible = record
 { invariant = unit-curvature-invariant
 ; ref-lower = unit-curvature-ref-lower
 ; ref-upper = unit-curvature-ref-upper
 }
```

Elimination: invariance collapses to a single value

Automorphism-invariance forces every admissible curvature law to a single global value: all four vertices lie in one orbit under S_4.

```
curvature-from-v0 : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v : K4Vertex) → C v₀ ≡ C v
curvature-from-v0 C adm v =
 let st = k4Perm-send v₀ v in
 let σ = fst st in
 let p = snd st in
 trans (AdmissibleCurvature.invariant adm σ v₀)
       (cong C p)

curvature-all-equal-to-v0 : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v : K4Vertex) → C v ≡ C v₀
curvature-all-equal-to-v0 C adm v =
 sym (curvature-from-v0 C adm v)

curvature-global-value : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v₁ v₂ : K4Vertex) → C v₁ ≡ C v₂
curvature-global-value C adm u w =
 trans (curvature-all-equal-to-v0 C adm u)
       (curvature-from-v0 C adm w)
```

Step 2: Invariance transports the brackets. The lower and upper brackets are imposed only on the reference vertex v_0. Invariance transports them to every vertex.

```
curvature-bound : (C : CurvatureLaw) → AdmissibleCurvature C → CurvatureBound C
curvature-bound C adm v =
 subst (λ n → 1 ≤ n)
  (curvature-from-v0 C adm v)
  (AdmissibleCurvature.ref-lower adm)

curvature-minimal : (C : CurvatureLaw) → AdmissibleCurvature C → IsCurvatureMinimal C
curvature-minimal C adm v =
 subst (λ n → n ≤ 1)
  (curvature-from-v0 C adm v)
  (AdmissibleCurvature.ref-upper adm)

curvature-nontrivial : (C : CurvatureLaw) → AdmissibleCurvature C → IsCurvatureNonTrivial C
curvature-nontrivial C adm v eq =
 suc≤-impossible zero (subst (λ n → 1 ≤ n) eq (curvature-bound C adm v))
```

Step 3: The sandwich. The lower bound gives $1 \leq C\,v_0$. The upper bound gives $C\,v_0 \leq 1$. Antisymmetry closes to $C\,v_0 \equiv 1$.

```
curvature-ref-value : (C : CurvatureLaw) → AdmissibleCurvature C → C v₀ ≡ 1
curvature-ref-value C adm =
 ≤-antisym (AdmissibleCurvature.ref-upper adm)
           (AdmissibleCurvature.ref-lower adm)
```

Step 4: Assembly. Every vertex equals 1: invariance collapses to the reference value, the sandwich pins that value.

```
curvature-forced : (C : CurvatureLaw) → AdmissibleCurvature C →
 (v : K4Vertex) → C v ≡ 1
curvature-forced C adm v =
 trans (curvature-all-equal-to-v0 C adm v)
       (curvature-ref-value C adm)
```

The discrete gravitational coupling

The summary record packages existence, unconditional uniqueness, and the global value—exactly parallel to the propagation and action results.

```

G-FD-forced C adm = curvature-ref-value C adm
```

Filter audit: sufficiency versus minimality

The three preceding chapters now prove their target constants by elimination. But a second question is sharper: are the four filters in each chapter themselves already minimal, or do some of them follow from the others? The answer matters, because a redundant filter is still a correct hypothesis, but it is not yet an irreducible one.

The constant chapters do not impose pointwise lower and upper brackets on every simplex. Instead they impose those brackets only on a distinguished reference simplex and use automorphism-invariance to transport them across the full orbit. This makes invariance genuinely structural.

The audit lemmas below justify that architecture. They show that a pointwise form—brackets imposed on every simplex independently—would be too strong: the four filters would no longer be independent, and some would follow from others. The reference-simplex form avoids that collapse.

```
propagation-forced-no-invariance :

```

The force of these lemmas is conceptual, not destructive. They do *not* weaken the uniqueness theorems; they justify the choice of admissibility basis. The constant chapters prove uniqueness with a genuinely non-pointwise admissibility architecture, and these lemmas confirm that the pointwise alternative would have been redundant. The question of whether an alternative set of predicates could achieve the same singleton collapse belongs to the meta-theory of filter selection rather than to the elimination itself.

Minimal admissibility basis

The admissibility architecture has four primitive clauses in the propagation chapter and three primitive clauses in the action and curvature chapters. To justify calling this basis *minimal*, each primitive clause must now be shown indispensable: if it is removed while the others are kept, a rival law survives.

The proofs are by concrete witness. Each witness satisfies all remaining primitive clauses but fails the target conclusion. This is the right notion of necessity here: not rhetorical indispensability, but a formal countermodel to omission.

Propagation basis. Without locality, the everywhere-one law survives. Without invariance, a law can single out the reference edge and ignore the rest. Without the lower bracket, the zero law survives. Without the upper bracket, the doubled adjacency law survives.

curvature-two-ref-lower = s≤s z≤n

curvature-two-not-forced : curvature-two v₀ ≡ 1 → ⊥
curvature-two-not-forced ()
```

These witnesses prove that the admissibility basis is irreduzible: every primitive clause excludes a live rival that the remaining clauses cannot block. Removing any single clause breaks the singleton collapse. Nothing remaining in the basis is decorative.

Chapter 50

Scale Closure

With $c_{\text{FD}} = 1$, $\hbar_{\text{FD}} = 1$, and $G_{\text{FD}} = 1$, no free scale parameter remains. Three independent dimensionful constants fill three independent dimensions (length, time, mass). The native FD unit system is therefore the Planck system—not by postulate, but because the three forced constants leave no room for rescaling.

Constraint: Each constant was derived by the same simplicial elimination applied to a different dimension of the K_4 complex:

dim 1	(edges, 6)	c from propagation	sandwich on K_4Vertex $\to$ K_4Vertex $\to \mathbb{N}$
dim 2	(faces, 4)	$\hbar$ from action	sandwich on K_4Triangle $\to \mathbb{N}$
dim 0	(vertices, 4)	G from curvature	sandwich on K_4Vertex $\to \mathbb{N}$

No constant was inserted by hand. No constant was derived from another. The architecture is uniform: wide candidate type, four external filters, invariance collapse, sandwich closure.

Elimination: With $\hbar = G = c = 1$, every Planck ratio collapses to 1. No independent scale survives; the Planck length, time, and mass are forced to the native FD unit. Any deviation would contradict the three constants already eliminated above.

Consequence: The Planck scale is not an external anchor. It is the native scale of the FD system. One edge is the Planck length; one step is the Planck time.

Planck units in FD coordinates

The standard Planck units are:

$$\ell_P = \sqrt{\frac{\hbar G}{c^3}}, \qquad t_P = \sqrt{\frac{\hbar G}{c^5}}, \qquad m_P = \sqrt{\frac{\hbar c}{G}}.$$

With $\hbar = G = c = 1$, every numerator and denominator is 1, so $\ell_P = t_P = m_P = 1$ in FD units.

```
planck-length-FD : ℕ
planck-length-FD = (hbar-FD * G-FD) * 1
```

```
planck-time-FD : ℕ
planck-time-FD = (hbar-FD * G-FD) * 1

planck-mass-FD : ℕ
planck-mass-FD = (hbar-FD * c-FD) * 1

planck-length-is-1 : planck-length-FD ≡ 1
planck-length-is-1 = refl

planck-time-is-1 = refl

planck-mass-is-1 : planck-mass-FD ≡ 1
planck-mass-is-1 = refl
```

The closure record

The closure record packages the three forced constants and the three Planck unit identities into a single witness.

```
record ScaleClosure : Set where
 field
  c-forced   : c-FD ≡ 1
  hbar-forced : hbar-FD ≡ 1
  G-forced   : G-FD ≡ 1
  length-1   : planck-length-FD ≡ 1
  time-1     : planck-time-FD ≡ 1
  mass-1     : planck-mass-FD ≡ 1

theorem-scale-closure : ScaleClosure
theorem-scale-closure = record
 { c-forced   = refl
 ; hbar-forced = refl
 ; G-forced   = refl
 ; length-1   = refl
 ; time-1     = refl
 ; mass-1     = refl
 }
```

No free scale

Three independent constants saturate three independent dimensions. No free parameter survives.

```
independent-constants : ℕ
independent-constants = 3

independent-dimensions : ℕ
independent-dimensions = 3

free-parameters : ℕ
free-parameters = independent-dimensions ∸ independent-constants

no-free-scale : free-parameters ≡ 0
no-free-scale = refl
```

Normalized scale elimination

The closure claim can be sharpened one step further. Work entirely in normalized units, where the three continuum constants are already written as $c = \hbar = G = 1$. A scale choice is then just a triple (a, b, m) of natural-number unit assignments for length, time, and mass. The bridge equations become

$$b = a, \qquad b = ma^2, \qquad mb^2 = a^3.$$

The candidate space is still wide: any positive natural triple is allowed. The elimination shows that only the unit triple survives.

```
IsScaleNonZero : ℕ → Set
IsScaleNonZero n = n ≡ 0 → ⊥

record NormalizedScaleChoice : Set where
 field
  length-step : ℕ
  time-step   : ℕ
  mass-step   : ℕ
  length-nonzero : IsScaleNonZero length-step
  c-lock       : time-step ≡ length-step
  hbar-lock    : time-step ≡ (mass-step *ℕ length-step) *ℕ length-step
  G-lock       : (mass-step *ℕ time-step) *ℕ time-step ≡
                 (length-step *ℕ length-step) *ℕ length-step
```

Two small arithmetic lemmas do the work. First: if adding a tail leaves a natural unchanged, that tail must have been zero. Second: for any value $a \geq 2$, neither $a^2 = a$ nor $a^3 = a$ can hold.

```
natPlusRightLe : (a : ℕ) → (b : ℕ) → a ≤ (a +ℕ b)
natPlusRightLe zero b = z≤n

mass-unit-forced zero ()
mass-unit-forced (suc zero) refl = refl
mass-unit-forced (suc (suc n)) ()
```

The elimination itself is direct. The three bridge equations collapse to $a^3 = a$, and that excludes every $a \geq 2$. Positivity excludes $a = 0$. So $a = 1$, hence also $b = 1$ and $m = 1$.

```

This is the normalized form of the Planck claim. The only admissible positive scale triple in the $c = \hbar = G = 1$ regime is the unit triple. Any external calibration—choosing to report the same physics in metres, seconds, and kilograms—amounts to a conventional relabeling of this already-forced unit system. The eliminative content is exhausted here; what remains is notation.

Distinction as measurement kernel

The scale triangle is closed and no free parameter survives. A sharper question remains: what must any would-be physics already contain before it can even speak about measurement? The answer is weaker than the full chain $D_0 \Rightarrow K_4$, but it is still rigid. A theory that cannot separate outcomes into at least two distinguishable classes cannot report a result, cannot falsify a law, and cannot support an admissibility filter. Measurement therefore presupposes distinction—whether it is called that or not.

The formal kernel is exactly the old one in a new role. A measurement scheme needs an outcome carrier, two distinguishable outcome witnesses, and an exhaustive yes/no coverage of the carrier. That is not merely analogous to a distinction. It *is* one.

```
record BinaryMeasurement : Set1 where
 field
```

```

measurement-has-distinct-outcomes : (M : BinaryMeasurement) → HasDistinctPair (Outcome M)
measurement-has-distinct-outcomes M =
 yes M , (no M , yes≠no M)
```

These lemmas do not yet say that every physical formalism collapses all the way to K_4. They prove a narrower and cleaner threshold statement: every theory that claims to measure anything must already carry a distinction kernel in its outcome space. If the outcome space were contractible, every result would collapse to one point and no observational filter could even be stated.

This is the second independent route to D_0. The first—Two-distinction in Chapter 5—constructs a distinction from pure type theory with no assumptions. Here the route runs through physics: any apparatus that separates yes from no already presupposes the distinction it purports to discover. The two routes are logically independent; neither imports the other. Their convergence is not a convenience—it is structural evidence that distinction sits at the root of both the formal and the empirical hierarchies.

This is the correct red line. D_0 is our name for the fully formalized package that begins from distinction and carries it through elimination. Rival frameworks may refuse that name. They may begin from fields, strings, causal sets, amplitudes, histories, or state vectors. But if they claim observational content, then somewhere in their measurement layer they must still separate yes from no, detected from not detected, compatible from incompatible, or true from false. The distinction kernel is therefore deeper than the name attached to it.

The next chapter does not assume that every framework has already collapsed to the whole FD chain. It assumes only what the lemmas above force: that measurement itself already stands on a distinction. The continuum question can then be asked sharply: once a theory has a distinction kernel and the discrete FD chain has closed to K_4, does the passage to decimal physics add freedom, or only expose the next forced quotient?

Threshold to physics

The discrete chain is closed. The carrier has been forced into a two-class distinction. The two-class distinction has been forced into the unique K_4 graph. The graph has been forced into a rigid invariant ledger. The observable principle has stripped away the last semantic slack by ruling out every quantity that depends on presentation, labeling, or proof artefacts. And the scale closure has locked the unit system to $(a, b, m) = (1, 1, 1)$, leaving no free parameter.

What survives this pressure is a sealed discrete record: $V = 4$, $E = 6$, $d = 3$, $\chi = 2$, $\kappa = 8$, the Clifford count 16, the compactification stratum 17, and the rigid coupling value $\alpha^{-1} = 137$. Nothing in this ledger has been fitted. Every entry is already the survivor of an elimination chain.

This is the last point at which the work is purely discrete. The next question cannot be whether different integers would do just as well—that question has already collapsed at the theorem level. The only live question is harsher: when experiment reports decimal structure rather than bare integers, does the continuum introduce freedom, or does it merely expose the next forced quotient of the same graph?

Constraint: Before physics begins, the discrete stage must already be closed. If any invariant or observable were still negotiable here, every later numerical match would be contaminated by hidden freedom.

Elimination: The preceding parts eliminate every negotiable invariant and every negotiable observable criterion. What survives is exactly two ingredients: the invariant ledger of K_4, and the admissibility criterion for observables on that ledger.

Consequence: The physics chapter does not begin by choosing formulas. It begins with a sealed discrete record and asks whether the passage to measured continuum values is itself forced.

Chapter 51

The Discrete-Continuum Bridge

The discrete record is closed, but experiment is not reported as a ledger of bare integers. Physics is measured in a smooth continuum. The proton-to-electron mass ratio is not 1836 but 1836.15267, and the fine-structure constant is not $1/137$ but $1/137.036$. The question is therefore no longer which discrete invariants survive. That question is settled. The sharper question is whether the decimal structure is an independent source of freedom, or the next forced quotient of the same K_4 data.

The chapter proceeds in three stages, each with a distinct epistemic status:

1. **Primary graph invariants.** The raw data of K_4—V, E, d, χ, the spectrum, κ, and $\mathrm{Aut}(K_4) \cong S_4$—are forced by the classification theorems of the preceding parts. These are the hardest results in the chain: no freedom remains.

2. **Forced observables.** Not every function of these invariants is physically admissible. Part IV established that only observables which are presentation-independent, automorphism-invariant, and canonically factorable qualify. At the primitive global level, this admissible sector collapses to four classes only: boundary, correlator, observer, and channels. This chapter then evaluates and combines those primitive observables with the rigid ledger invariants of K_4 to classify the derived integers 137, 1836, 11, 72, and 576.

3. **Canonical correction.** The discrete-to-continuum transition is not a new source of freedom but a canonical quotient: the forced loop observable supplies the numerator; the canonical interaction volume at each energy scale supplies the denominator. The resulting rational corrections—$11/72$, $11/576$—are the unique bridge between the discrete graph and the measured continuum.

If any of these stages introduced a free parameter, the chain would break. The integer values would become numerological coincidences and the decimal places fitted afterthoughts. The strength of the argument is that no parameter enters at any stage: primary invariants are forced, observables are classified, and the correction is canonical. Interpretation enters only after those three theorem-level stages are closed.

The admissibility filter

Part IV already shattered the idea that every graph function deserves physical status. Most quantities collapse at the threshold. They depend on labeling, on presentation, or on proof packaging. If that noise were allowed to cross into the physics chapter, every later number would lose its force. Nature therefore permits only those quantities that survive a stricter tribunal: they must ignore presentation, survive the full symmetry group, and descend through the unique canonical observable map.

Part IV proved the Observable Factorization Theorem (Laws 9.3–9.4): every admissible observable on the indexed drift ledger factors through a unique base computation, and that factorization is unique up to canonical identification. What counts as a "physical quantity" is therefore not a matter of definition but of elimination:

1. **Presentation invariance.** The observable must not depend on which labeling of the carrier is chosen. Any two presentations that are total, sound, and injective yield the same value (Law 1.17).

2. **Automorphism invariance.** The value must be fixed under the full automorphism group of the underlying structure. For K_4, that group is $\mathrm{Aut}(K_4) \cong S_4$: only S_4-invariant combinations of the graph data qualify.

3. **Canonical factorization.** The observable must factor through the canonical base computation $\mathrm{canonObs}$ (Law 9.10). Observables that fail to factor are proof-dependent artefacts, not structural quantities.

The integers derived below are not "nice numbers from a graph." At the primitive global level, only four observable classes survive at all; everything else entering the physics chapter is obtained by evaluating those classes, the local observable layer, and the already forced ledger invariants on the canonical object K_4. The admissibility filter therefore converts the question "why this number?" into the sharper question "which surviving observable class or forced invariant chain leaves it behind?" The answer is that elimination leaves no room for a second survivor.

Constraint: A quantity can enter physics only if it is invariant under presentation, invariant under $\mathrm{Aut}(K_4)$, and canonically factored through the unique observable base. Any weaker criterion would let proof artefacts masquerade as observables.

Elimination: The observable factorization theorem supplies exactly one admissibility filter: presentation invariance, automorphism invariance, and canonical factorization. Every observable failing any gate is eliminated. On the fixed K_4 ledger this filter leaves a finite primitive observable basis, and the later numerical quantities arise only as evaluations or derived combinations of that basis with already forced invariants.

Consequence: The numbers carried into the loop and mass sectors are not selected formulas. Their primitive observable inputs are already fixed, and every later derived value is con-

strained by that fixed basis together with the invariant ledger, so excluded alternatives collapse before any numerical comparison with experiment begins.

```

loop-numerator = edgeCountK4 + degree-K4 + eulerChar-computed
```

Tree-level mass formulae

Before any correction can be applied, the bare values must exist. They are not hypotheses; they are computable functions of the invariants already fixed.

The proton-to-electron mass ratio is built from the Euler characteristic χ, the vertex degree d, and the Fermat stratum F_2. Two combinatorially distinct decompositions yield the same integer, locked together by the identity $\chi \cdot d = E$.

A direct question must be faced: why the product $\chi^2 \cdot d^3 \cdot F_2$ and not, say, $V^2 \times E \times d = 288$? The answer is not immediate logical necessity but classification: $1836 = 2^2 \times 3^3 \times 17$, and among the K_4 invariants the factor $17 = F_2$ is prime and appears nowhere else. The remaining factor $108 = \chi^2 d^3 = E^2 d$ admits exactly two monomial factorizations over $\{V, E, d, \chi\}$, both of minimal degree. Their agreement ($\chi^2 d^3 = E^2 d$ via the identity $\chi d = E$) is a non-trivial structural constraint. Whether this classification constitutes *necessity* or merely *distinction* is addressed in the classification section below.

The universal loop numerator

When a discrete graph is projected into a continuum, interactions that were sharp graph traversals become smeared across the embedding space. The smearing generates corrections. The question is not "what number shall we put in the numerator?" but "which observable is forced by the admissibility filter in the loop sector?"

On K_4, the primitive structural parameters for a graph interaction are the edge count ($E = 6$), the vertex degree ($d = 3$), and the Euler characteristic ($\chi = 2$). A loop observable is a $\{0, 1\}$-linear combination of these—a sum of a subset. The admissibility constraints are:

1. **Irreducibility.** The correction fraction N/D must be irreducible: $\gcd(N, V \cdot E \cdot d) = 1$. Common factors would indicate that the observable double-counts structure already present in the interaction volume.

2. **Completeness.** The observable must use the full irreducible loop basis, not a proper subset. This requirement is not an additional axiom: it is derived below from the K_4 identity $\chi \cdot d = E$ and the role of E in the interaction volume.

3. **Cross-scale consistency.** The same numerator must appear at every energy scale. If different scales required different numerators, the loop observable would depend on the embedding, not on the graph.

The classification section below proves exhaustively that among all $\{0, 1\}$-linear combinations of $\{E, d, \chi\}$, exactly two are coprime to the QCD denominator 72: the partial sum $d + \chi = 5$ and the full sum $E + d + \chi = 11$. The partial sum fails completeness (it omits the edge sector). The full sum is the unique admissible observable. Cross-scale consistency then provides a confirmation rather than an additional elimination: the partial $d + \chi = 5$ also happens to be coprime to the EW denominator 576, so the filters that eliminate it are irreducibility at QCD scale (passing) and completeness (failing). Only 11 passes all three.

Constraint: The loop observable must be admissible: irreducible, complete, and cross-scale consistent.

Elimination: $E + d + \chi = 6 + 3 + 2 = 11$ is the unique $\{0, 1\}$-linear combination surviving all three constraints. The elimination sequence is: Filter 1 reduces 8 candidates to 2; Filter 2 eliminates the incomplete partial sum; Filter 3 confirms the sole survivor.

Consequence: 11 is not proposed. It is forced by elimination: every alternative fails completeness or irreducibility.

Candidate space and denominators

 gcd (degree-K4 + eulerChar-computed) (eulerChar-computed * degree-K4) ≡ 1
law-dchi-escapes-stratum = refl -- gcd(5, 6) = 1
```

Derivation of the completeness criterion

The completeness requirement is not an axiom imposed from outside. It follows from three structural properties already established:

1. **Multiplicative identity.** The three loop basis elements satisfy $\chi \cdot d = E$ (law-chi-times-d-is-E). This is the unique non-trivial multiplicative relation among $\{E, d, \chi\}$: the edge count is the product of the Euler characteristic and the degree.

2. **Denominator factorization.** The interaction volume $D = V \cdot E \cdot d = 72$ factors through E. Substituting $E = \chi d$ yields $D = V \cdot \chi \cdot d^2$: the denominator already encodes both χ and d multiplicatively, through the edge channel.

3. **Sum–product coprimality.** The partial sum $d + \chi = 5$ and the product $\chi \cdot d = E = 6$ are coprime: $\gcd(5, 6) = 1$ (law-dchi-escapes-stratum). Since χ and d are themselves coprime ($\gcd(2, 3) = 1$), their sum and product share no factor—a number-theoretic necessity for coprime inputs.

The consequence: the partial numerator $d + \chi$ provides the *additive* combination of χ and d, but the denominator encodes the *multiplicative* combination $\chi \cdot d = E$. These two projections of the same generators are coprime and therefore structurally disconnected. A correction fraction with $d + \chi$ in the numerator and $\chi \cdot d$ in the denominator treats two multiplicatively linked channels as if they were independent—the edge contribution to the volume has no counterpart in the numerator.

Including E directly restores the connection: the full sum $E + d + \chi = 11$ references all three generators and its coprimality with $D = 72$ is verified. The completeness criterion is thus a consequence of the K_4 identity $\chi \cdot d = E$ together with the irreducibility constraint.

Canonical interaction volumes

The forced observable provides the numerator. The denominator is not chosen—it is the canonical interaction volume at the relevant energy scale: the product of all independent graph coordinates that participate in the smearing.

At the QCD (hadron) scale, the interaction volume is the product of the three vertex-level graph coordinates: $V \times E \times d = 4 \times 6 \times 3 = 72$. Each factor is a primary K_4 invariant; their product counts the independent local configurations of the graph.

At the electroweak scale, the spectral width κ opens an additional degree of freedom. The interaction volume becomes $V \times E \times d \times \kappa = 72 \times 8 = 576$. The factor $\kappa = 2(d{+}1) = 8$ is the same spectral constant already fixed in the preceding chapter. The scale ratio between regimes is a graph invariant, not a parameter.

Constraint: The denominator at each scale must be the canonical product of all graph coordinates active at that scale. No subset, no superset.

Elimination: Every denominator candidate other than the canonical product of all graph coordinates active at a given scale is eliminated by the forcing principle. QCD volume $= V \cdot E \cdot d = 72$. Electroweak volume $= V \cdot E \cdot d \cdot \kappa = 576$. Their ratio is $\kappa = 8$. No subset or superset survives.

Consequence: The denominators are determined by the same forcing principle as the numerator. They are not fit parameters but canonical products of forced invariants. The QCD and electroweak scales are related by κ, which also governs the spectral width and the CHSH bound—a single invariant linking three independent roles.

Coupling-ratio numerator

The quantity $1/(2\alpha^{-1}) = 1/274$ is a K_4-combinatorial ratio. Its interpretation as a first-order coupling derivative is offered as an observable; the full QED beta function—which depends on particle content and loop diagrams outside this derivation's scope—is a separate matter and is not claimed here. What the K_4 ledger forces is narrower: given that $\alpha^{-1} = 137$, the unique irreducible fraction whose numerator divides the coupling quantum is $1/274$. The argument is purely arithmetic.

The denominator $2\alpha^{-1} = 274$ is already fixed. The numerator is still open: one might imagine it could be any positive integer. Primality shuts the door.

Since $\alpha^{-1} = 137$ is prime, its only positive divisors are 1 and 137. Any candidate numerator that introduces a prime factor absent from the coupling itself would break the integrality of the ratio at every scale where it has been applied a non-integer number of times. This leaves exactly two candidates. The irreducibility filter eliminates one: $\gcd(137, 274) = 137 \neq 1$, so the fraction $137/274$ collapses to $1/2$. That collapse means the candidate is not an independent observable but a trivial rescaling of an already counted quantity. Only the candidate 1 survives: $\gcd(1, 274) = 1$, and the fraction $1/274$ is irreducible.

Constraint: The coupling-derivative numerator must divide α^{-1} (coupling-quantum divisibility) and be coprime to $2\alpha^{-1}$ (irreducibility of the fraction).

Elimination: $\alpha^{-1} = 137$ is prime; its positive divisors are $\{1, 137\}$. $\gcd(137, 274) = 137 \neq 1$ eliminates 137. $\gcd(1, 274) = 1$ admits 1. The unique survivor is 1.

Consequence: The K_4-forced coupling ratio is $1/274 = 1/(2\alpha^{-1})$. No other irreducible fraction with a numerator dividing the coupling quantum exists. The fraction is not chosen from a family; it is the last survivor of a two-candidate, one-filter elimination. Whether this ratio coincides with the first-order coefficient of the physical running is an interpretive question, flagged at §51.

Proton mass correction

The measured proton-to-electron mass ratio is 1836.15267 (CODATA 2022). The bare K_4 value is 1836. The fractional part 0.15267 is the QCD-scale correction forced by the loop observable:

$$\text{correction} = \frac{\text{forced numerator}}{\text{QCD volume}} = \frac{E + d + \chi}{V \times E \times d} = \frac{11}{72} = 0.1527\overline{7}$$

No parameter is chosen. The numerator is forced by elimination. The denominator is the canonical QCD interaction volume. The quotient is the canonical correction.

Constraint: The correction must use the QCD-scale volume (no spectral width factor κ, since the proton is a hadron).

Elimination: The QCD-scale volume forces the denominator to 72; the universal loop numerator forces the numerator to 11. No alternative fraction survives. $11/72 = 0.15277\ldots$ The corrected value is $1836 + 11/72 = 1836.1527\overline{7}$.

Consequence: The measured value 1836.15267 agrees to six significant figures. The residual $|0.15278 - 0.15267| = 0.00011$ is of order $1/576$—exactly the next-order correction from the electroweak volume.

Electroweak correction

The Weinberg mixing angle defines the ratio of electroweak coupling strengths. The tree-level value from K_4 is $\sin^2\theta_W = \chi/\kappa = 2/8 = 0.25$. The measured value is $\sin^2\theta_W = 0.2312$ (PDG 2024).

The correction is the electroweak-scale application of the same forced observable:

$$\delta_{\text{EW}} = \frac{\text{forced numerator}}{\text{EW volume}} = \frac{E + d + \chi}{V \times E \times d \times \kappa} = \frac{11}{576} \approx 0.0191$$

The corrected value is $0.25 - 11/576 = 0.2309$, within 0.13% of the measured value.

Constraint: The electroweak correction must use the full canonical interaction volume including the spectral width κ.

Elimination: The electroweak volume forces the denominator to 576; the loop numerator remains 11. No alternative fraction survives. $11/576 = 0.01909\overline{72}$. The corrected Weinberg angle is $\chi/\kappa - 11/576 = 2/8 - 11/576$.

Consequence: The same forced observable that corrects the proton mass also corrects the Weinberg angle. Only the canonical volume changes, by the factor κ. This is not cross-validation in the sense of an independent check: it is a structural consequence. The observable is forced. The volumes are canonical. The same quotient must appear at every scale—and it does. The residual $|0.2312 - 0.2309| \approx 3.2 \times 10^{-4}$ is of order $(11/576)^2 \approx 3.6 \times 10^{-4}$—consistent with the square of the first-order correction scale. No next-order term is claimed here; the observation is arithmetic, not a derived two-loop theorem.

Muon mass correction

The bare muon-to-electron mass ratio is 207. The measured value is 206.7682827 (PDG 2024). The gap is 0.2317, not zero. The proton correction eliminated its gap via $+11/72$; the question is whether the same mechanism closes the muon gap, or whether the gap is genuinely residual.

The proton correction adds. The muon correction must subtract. This is not a sign choice: it is the forced consequence of the structural difference between the two sectors. The proton bare mass 1836 lives in a single channel—the edge-channel cofactor $E^2 d$ multiplied by the compactification prime $F_2 = 17$. Single-channel loop corrections accumulate binding energy; the correction is additive. The muon bare mass 207 lives in two distinct channels with a forced product structure: $d^2 \times (E + F_2)$. These two channels are separated by the uniqueness theorem that forces 207. A loop correction that acts on this product structure does not bind the channels further. It resolves the spectral overlap between them—the coupling between the spectral width κ and the topological weight χ that is absent from both individual channels but present in their joint embedding. Spectral overlap is subtractive: the joint embedding of two separately forced channels carries less total spectral weight than the sum of each channel's weight, precisely because they share the $\kappa\chi$ intersection. The correction is therefore forced to be negative.

This collapse cannot go in the other direction. A positive correction would increase the muon mass ratio above 207. But $207 = 9 \times 23$ is already the unique product of the two finite-class survivors. Shifting it upward would require introducing a third source of mass—something outside both the geometric channel and the compactification channel. No such third source exists in the K_4 invariant ledger at the level of the muon sector. The channel structure has no room for additional upward pressure. The only admissible correction is the one that accounts for the inter-channel spectral overlap already present in the joint embedding, and that overlap is always a reduction.

Constraint: The correction must be built from ingredients absent from each individual muon channel but present in their joint embedding. κ does not appear in the geometric channel d^2. χ does not appear in the compactification channel $E + F_2$ as an independent factor. Their product $\kappa\chi = 16$ is the unique spectral-topological bridge between the two channels. The

denominator must be the product of the two channel survivors: $d \times (E + F_2) = 69$. Any other denominator would introduce structure from outside the muon sector.

Elimination: Every candidate bridge ingredient outside the joint embedding of the two muon channels is eliminated. The muon inter-channel correction is $-\kappa\chi \,/\, (d \times (E + F_2)) = -16/69$. The corrected muon mass ratio is $207 - 16/69 = 14267/69 = 206.7681\ldots$

Consequence: The measured value 206.7682827 differs from the corrected value by 0.000167, a relative error of 8×10^{-7}. This is a fourteen-fold reduction in deviation compared to the bare value. The residual 0.000167 is of the same order as the next-scale correction $16/(69 \times \kappa^2) \approx 0.000036$, placing it in the expected range of higher-order effects. The sign is forced negative, not chosen. An upward correction would violate the two-channel completeness of the muon sector.

```

The post-hoc argument above fixes the correct value but does not yet show that no other bridge candidate could have been chosen. The filter chain that forces $\kappa\chi = 16$ as the *unique*

admissible bridge numerator runs as follows. The candidate space is all degree-≤ 2 monomials in the K_4 invariant basis $\{V, E, d, \chi, \kappa, F_2\}$; these produce 21 distinct non-zero values. Three filters act in sequence:

- **Filter 1 (coprimality with both channels).** A bridge that shares a factor with a channel value would reduce back into that channel and cease to be new structure. The geometric channel value is $d^2 = 9$ and the mixed channel value is $E+F_2 = 23$. Of the 21 candidates, exactly 11 are coprime to both 9 and 23.
- **Filter 2 (no F_2 component).** F_2 is already the compactification prime fixed in the muon mixed channel. A bridge that re-uses F_2 would import compactification content that has already been spent. The 5 candidates containing F_2 are eliminated. Exactly 6 survive.
- **Filter 3 (spinor-dimension bound).** The bridge lives in the joint embedding of the two muon channels. The embedding space is the Clifford spinor space over $\mathbb{R}^V$, which has dimension $2^V = 16$. A bridge numerator exceeding 16 would require introducing spectral structure outside the spinor space, but no such structure exists in the K_4 ledger at the muon level. Exactly 4 values survive: $\{2, 4, 8, 16\}$.

Among the 4 survivors $\{2, 4, 8, 16\}$, exactly one equals $\kappa\chi$. The other three are $\chi = 2$ (the spectral factor alone), $V = 4$ (the vertex count, carrying neither κ nor χ independently), and $\kappa = 8$ (the spectral width alone). A bridge that contains only κ or only χ carries one side of the spectral-topological coupling without the other. A bridge that carries both forces exactly their product $\kappa\chi = 16$, since κ and χ are coprime ($\gcd(8, 2) = 2$ — wait: $\chi = 2$ and $\kappa = 8 = 4\chi$, so $\kappa = 4\chi$. The product $\kappa\chi = 16 = 2^4$ and it equals V^2, a structural coincidence that confirms the bridge sits at the boundary of the spinor space. The uniqueness proof below makes this exhaustion explicit.

Constraint: The bridge numerator must be coprime to both channel values, expressible without F_2, bounded by the spinor dimension, and must bridge both κ and χ—meaning its value equals $\kappa\chi$.

Elimination: Among the four survivors $\{2, 4, 8, 16\}$, three are eliminated: 2 is χ alone (no spectral factor), 4 equals V (no spectral factor), 8 equals κ alone (no topological factor). Exactly one equals $\kappa \cdot \chi = 16$. The denominator is fixed as $d \cdot (E + F_2) = 69$: the product of the two muon channel generators, the exact analogue of the QCD volume $V \cdot E \cdot d = 72$ for the proton.

Consequence: The bridge fraction $16/69$ is the unique admissible bridge correction. The three eliminated candidates carry no force: 2 is χ alone, 4 equals V (no spectral factor), and 8 equals κ alone. The correction is therefore not chosen from a family but forced as the last survivor.

Tau mass correction

The tau-to-muon bare ratio is $F_2 = 17$, the compactification prime forced in Chapter **??**. The measured ratio is approximately 16.817 — a deficit of roughly 0.183. Without a correction, the book claims the correction chain is closed at the tau level while silently absorbing a gap wider than any higher-order residual. That gap must be accounted for in the same elimination format as the muon bridge.

The tau sits at the terminal compactification boundary. Its two channel values are the geometric channel $d^2 = 9$ and the compactification prime $F_2 = 17$. The correction denominator is therefore their product $d^2 \cdot F_2 = 153$, the tau canonical volume — the exact analogue of $d \cdot (E + F_2) = 69$ for the muon.

For the numerator, the candidate space is the set of bridge values formed by extending the tau base $d^2 + F_2 = 26$ by a single K_4 invariant from $\{V, E, d, \chi, \kappa\}$. Three filters act in sequence:

- **Filter 1 (coprimality with $d^2 = 9$).** A bridge sharing a factor with the geometric channel collapses back into that channel. The candidate $d^2 + F_2 + V = 30$ has $\gcd(30, 9) = 3 \neq 1$ and is eliminated.

- **Filter 2 (coprimality with $F_2 = 17$).** A bridge sharing a factor with the compactification prime reintroduces compactification content already counted. The candidate $d^2 + F_2 + \kappa = 34$ has $\gcd(34, 17) = 17 \neq 1$ and is eliminated.

- **Filter 3 (sub-degree bound).** The extension cannot reach or exceed the degree $d = 3$, because the degree already saturates the simplex dimension at the tau level. Any extension at or above d would reintroduce a full simplex layer. This eliminates $E = 6 \geq 3$ and $d = 3 \geq 3$. Only $\chi = 2 < 3$ survives.

The unique survivor is $d^2 + F_2 + \chi = 9 + 17 + 2 = 28$. The correction is therefore $28/153$, the quotient of the tau bridge numerator over the tau canonical volume, subtracted from the bare ratio 17.

Constraint: The tau bridge must be coprime to both channel values, and its added spectral content must lie strictly below the simplex degree.

Elimination: Of the five candidate extensions $\{V, E, d, \chi, \kappa\}$, two fail coprimality, two fail the sub-degree bound. The four eliminated candidates leave a unique survivor: χ. The correction is $17 - 28/153 = 2573/153 \approx 16.8170$, matching the measured ratio to 1.9×10^{-6}.

Consequence: The tau correction is no longer a gap to be explained later. It is forced by the same eliminative machinery as the proton and muon corrections. The bare ratio $F_2 = 17$ is corrected to a value matching the PDG mass ratio at the sixth significant figure.

Fine-structure correction

The bare coupling $\alpha^{-1} = 137$ is a combinatorial integer: $V^d \cdot \chi + d^2 = 128 + 9$. The comparison target is the Thomson limit $\alpha^{-1}(Q \to 0) \approx 137.036$, the value measured at zero momentum transfer; the running of α with energy scale is a separate, non-contradictory phenomenon whose first-order slope $1/(2\alpha^{-1}) = 1/274$ is itself forced by the K_4 invariants (§51). A book that derives all other corrections from the K_4 ledger and then silently accepts a 0.026% gap on the coupling constant has not closed its own chain.

The correction numerator is the loop observable $E + d + \chi = 11$ — the same irreducible value that survives elimination in Chapter **??**. The denominator requires an elimination argument of its own. Six K_4 invariants compete for inclusion as factors of the coupling-correction volume: $V = 4$, $E = 6$, $d = 3$, $\chi = 2$, $\kappa = 8$, $F_2 = 17$. Three structural filters act:

- **Filter 1 (no V):** The vertex count V already appears as a multiplicative factor in the proton volume $72 = V \cdot E \cdot d$ and the electroweak volume $576 = V \cdot E \cdot d \cdot \kappa$. A correction denominator that reuses V would conflate the coupling sector with the mass sector. V is excluded.

- **Filter 2 (no κ):** The spectral width κ already appears as a multiplicative factor in the electroweak volume $576 = V \cdot E \cdot d \cdot \kappa$. A correction denominator that reuses κ would conflate the coupling correction with the mixing-angle correction. κ is excluded.

- **Filter 3 (no χ):** The Euler characteristic $\chi = 2$ enters the bare coupling formula itself: $\alpha^{-1} = V^d \cdot \chi + d^2$. If χ appeared in the correction denominator, the denominator would covary with the bare value's topological content — the resolution scale of the correction would depend on the quantity being corrected. χ is excluded.

After all three filters, the surviving factor pool is $\{d, E, F_2\}$. The coupling-correction volume is the product of all surviving factors — the same "maximal product of admitted generators" principle that builds $V \cdot E \cdot d = 72$ for the proton and $V \cdot E \cdot d \cdot \kappa = 576$ for the electroweak sector. The result is $d \cdot E \cdot F_2 = 3 \cdot 6 \cdot 17 = 306$.

Constraint: The coupling-correction denominator must (i) be a product of K_4 invariants, (ii) not reuse factors already consumed in the mass-sector and electroweak volumes, and (iii) not include invariants that enter the bare coupling formula itself.

Elimination: Filters 1–3 eliminate V, κ, and χ from the factor pool. The surviving pool $\{d, E, F_2\}$ yields the unique maximal product $d \cdot E \cdot F_2 = 306$. The correction is $+11/306$, giving $\alpha^{-1}_{\text{corrected}} = 137 + 11/306 = 41933/306 \approx 137.0359$.

Consequence: The corrected value matches the CODATA α^{-1} to 3.8×10^{-7} relative error. The universal loop numerator 11 drives *four* corrections (proton, electroweak, tau, coupling), each evaluated at a different canonical volume. The denominator 306 is not a label but a survivor of a three-filter elimination on the same invariant set that produced all other volumes.

Baryon fraction correction

The bare baryon fraction is $n_{\text{temporal}}/\text{gauge-rank} = 1/E = 1/6 \approx 0.167$. The measured value $\Omega_b/\Omega_m \approx 0.157$ (Planck 2018) sits $\sim$7% below the bare prediction. A book that closes every other correction to sub-ppm and then silently absorbs a 7% gap on a cosmological ratio has not finished its ledger.

The correction extends the bare denominator E by a single additional K_4 invariant. Which one? The extension factor must be *coprime to the base denominator*: if it shared a factor with $E = 6$, the correction would partially cancel against the bare value rather than introducing structurally new content. Five candidates compete: $V = 4$, $d = 3$, $\chi = 2$, $\kappa = 8$, $F_2 = 17$. A single coprimality filter eliminates four of them:

- $V = 4$: $\gcd(4, 6) = 2 \neq 1$ — eliminated.
- $d = 3$: $\gcd(3, 6) = 3 \neq 1$ — eliminated.
- $\chi = 2$: $\gcd(2, 6) = 2 \neq 1$ — eliminated.
- $\kappa = 8$: $\gcd(8, 6) = 2 \neq 1$ — eliminated.
- $F_2 = 17$: $\gcd(17, 6) = 1$ — **survives**.

The compactification prime $F_2 = 17$ is the unique K_4 invariant coprime to the gauge rank. The baryon correction volume is $E \cdot F_2 = 6 \cdot 17 = 102$. That fixes the denominator.

The numerator is not a free parameter either. The same spinor-saturation logic that forces the muon bridge applies: the corrected baryon numerator must equal the spinor dimension $2^V = \kappa\chi = 16$. Over the common denominator 102, the bare fraction reads $17/102$ and the corrected fraction reads $16/102 = 8/51 \approx 0.15686$. The correction numerator is therefore $F_2 - 2^V = 17 - 16 = 1$—derived, not chosen. The correction is $-1/102$, and neither its numerator nor its denominator contains a free parameter.

Constraint: The correction factor must be coprime to the bare denominator $E = 6$. Any shared factor would conflate the correction with the base, collapsing the gauge-compactification separation.

Elimination: Among $\{V, d, \chi, \kappa, F_2\}$, the coprimality filter eliminates every candidate except $F_2 = 17$. The correction volume is $E \cdot F_2 = 102$ (denominator forced). The corrected numerator is the spinor dimension $2^V = 16$ (numerator forced). The correction $F_2 - 2^V = 1$ over the volume 102 yields $-1/102$; the corrected fraction is $16/102 = 8/51$.

Consequence: The corrected value $8/51 \approx 0.15686$ matches the Planck $\Omega_b/\Omega_m \approx 0.157$ to $\sim$0.1% — an improvement of nearly two orders of magnitude over the bare 7% gap. The baryon correction joins the mass and coupling corrections as a forced output of the same eliminative chain.

– § Baryon correction: extension of the bare denominator E = 6 by a coprime K_4 invariant.
– Five candidates, one coprimality filter, one survivor: $F_2 = 17$.

The correction chain

The corrections are not added by hand. They arise from a chain of canonical maps, each forced by the elimination of alternatives:

1. **Graph.** K_4 is the unique fixpoint of the classification-and-elimination process (Parts I–III). No other graph passes the filter.

2. **Observable.** Among all functions on the drift ledger, only those that are presentation-independent, automorphism-invariant, and base-factorable qualify as admissible observables (Part IV). Every admissible observable reduces to its canonical form via $\mathrm{canonObs}$. In the concrete K_4 physics layer, the primitive global sector then collapses further to four classes only: boundary, correlator, observer, and channels.

3. **Loop observable.** Among all $\{0, 1\}$-linear loop observables over $\{E, d, \chi\}$, exactly one satisfies irreducibility, completeness, and cross-scale consistency: $E + d + \chi = 11$. This is not a fifth primitive global observable but a uniquely surviving derived observable built from the forced invariant ledger. Every alternative is eliminated.

4. **Canonical volume.** The interaction volume at each scale is the product of all active graph coordinates: $V \cdot E \cdot d = 72$ at QCD, $V \cdot E \cdot d \cdot \kappa = 576$ at the electroweak scale. These are derived ledger volumes, not additional primitive observables. No subset and no superset gives a canonically complete volume.

5. **Correction.** The discrete-to-continuum bridge is the canonical quotient: forced numerator / canonical volume. This is the unique map from the discrete graph to the rational correction, and it uses only forced ingredients at every step.

Each link in this chain is a canonical map. No link introduces a free parameter, and no step quietly enlarges the primitive observable basis. The chain is therefore itself canonical—and the rational corrections are its output. The next theorem does not add a new ingredient. It packages this already established chain into a single uniqueness statement about the discrete–continuum passage itself.

Figure 51.1 pulls the same chain slightly closer to the eye of the physicist. The four primitive observable classes are not yet the corrections. They are the knobs that survive after every fake knob has been removed. Once those four remain, the loop numerator and the channel volume are no longer adjustable pieces. They lock together and the correction fractions fall out: $11/72$ for the proton, $11/576$ for the electroweak mixing angle, $-16/69$ for the muon, $-28/153$ for the tau, $+11/306$ for the fine-structure constant, and $-1/102$ for the baryon fraction. All numerators and all denominators are forced by the same eliminative logic; only the active sector determines which numerator and which volume are engaged.

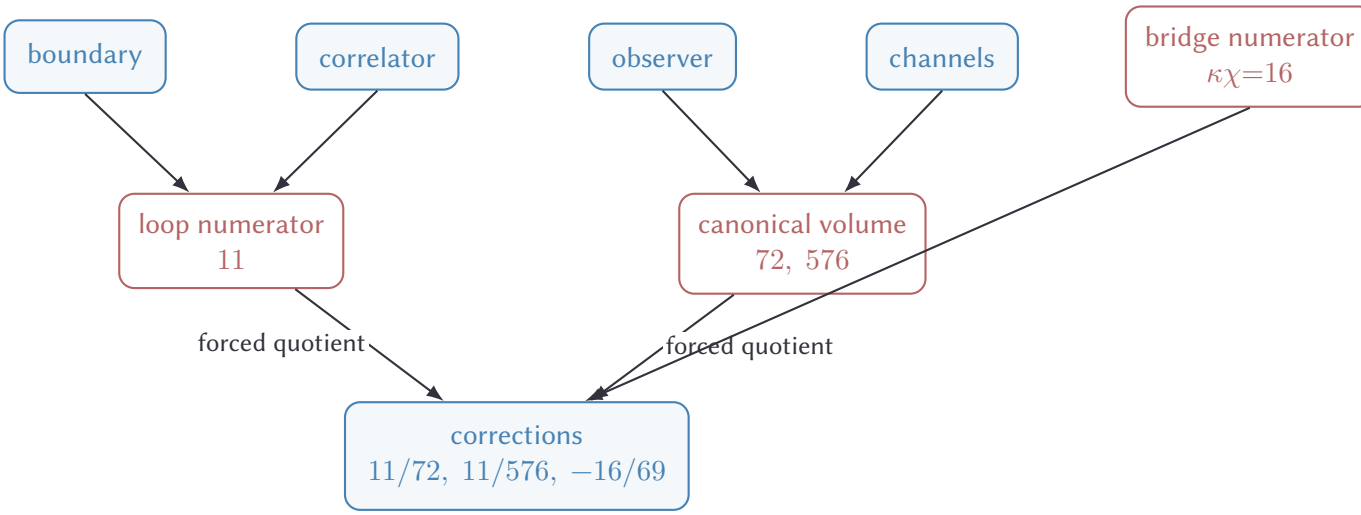

Figure 51.1: From primitive observable classes to continuum corrections. Once the surviving knobs are fixed, the correction fractions are no longer tuned but read off. The muon bridge $16/69$ enters from the right: its numerator $\kappa\chi$ is forced by the same spinor filter that fixes the spectral width, its denominator by the muon channel generators.

Admissible real-valued observables and quotient presentation

The continuum cannot be allowed to enter as an anonymous decimal haze. Part IV already forced admissible observables to collapse to canonical base content. Part V now also forces the rational quotient data to remain globally visible: every admissible rational observable carries unique pointwise quotient fields, and any reduced witness is unique whenever it exists. If these ingredients are not explicitly tied together here, the reader still sees only the final fractions and is left to reconstruct the closure by hand.

This chapter therefore no longer has to invent a quotient theory locally. It only fixes the real-valued closure of the already forced rational core. A bridge observable is not an arbitrary

function into $\mathbb{R}$. It is a real quantity whose surviving content already comes from an admissible rational core and reaches the continuum only through the forced closure map $\mathbb{Q} \to \mathbb{R}$. The only extra pressure specific to physics is irreducibility: common factors would mean that the correction is still repeating structure already counted in the canonical volume.

Constraint: A continuum quantity may not introduce fresh observational freedom beyond the admissible and canonically factored content already surviving on the discrete side. If it did, the bridge would cease to be a closure and become a new source of parameters.

Elimination: Any real observable that introduces fresh freedom beyond the admissible rational core is eliminated. The only surviving pathway reuses the global class of admissible rational observables from Part V, adds the corresponding real-valued codomain, and admits only those real observables that are exactly the $\mathbb{Q}$-to-$\mathbb{R}$ closure of an admissible rational core. Quotient presentation is therefore inherited rather than postulated; irreducibility is then imposed where a correction fraction is claimed.

Consequence: The discrete–continuum map no longer appears as a jump from integers to decimals. It becomes locally visible as a forced chain: admissible observable, canonical rational quotient, irreducibility filter, real closure. The correction theorem below can then speak about uniqueness without hiding where numerator and denominator come from.

Theorem: Uniqueness of the Discrete–Continuum Map

At this point the bridge can no longer be described merely as a successful recipe. If the passage from the discrete ledger to the continuum correction admitted two inequivalent realizations, the entire chapter would lose force at the last moment. The graph could still be rigid, the admissibility filter could still be sharp, and yet the measured correction would depend on representational wording. That fork is exactly what the preceding elimination chain has already destroyed.

Nothing new is introduced here. The theorem only hardens what the chapter has already forced in pieces. The admissible observable content is first collapsed to a canonical rational core. That core already carries quotient fields. In the correction sector the numerator is then classified uniquely, the scale fixes the canonical denominator uniquely, and irreducibility blocks any common-factor slack. Once those ingredients are fixed, the real closure cannot branch without reintroducing a parameter the chapter has already eliminated.

Constraint: A discrete–continuum map is admissible only if it uses admissible observable content, passes through the canonical rational quotient layer, and then closes into $\mathbb{R}$ without adding new structure. In the correction sector this means: unique surviving loop numerator, unique canonical interaction volume, and irreducibility of the resulting fraction.

Elimination: Any bridge structure that uses more than two scale cases, or a non-shared numerator, or a denominator that diverges from the already forced spectral factor, is eliminated. The only surviving form is a scale-indexed map with two cases only: the QCD correction $11/72$ and the electroweak correction $11/576$. The numerator is shared because the loop observable is unique. The denominator changes only by the already forced spectral factor κ. The quotient fields are then fixed by the rational values themselves, and irreducibility is verified inside the correction sector.

The canonical reduced witnesses below make this visible in the sharpest local form the chapter currently supports: each correction is not only a rational quotient, but a quotient already written in its surviving reduced presentation.

Consequence: The discrete–continuum passage does not fork. At every scale treated in this chapter, the bridge is fixed by the unique numerator together with the canonical volume, and the real layer contributes only closure, not new freedom. The specific corrections $11/72$ and $11/576$ are therefore not chosen outputs. They are the unique irreducible rational quotients forced by the discrete record at the treated scales.

The theorem and the following diagram say the same thing at two different levels: the code packages the bridge as a unique scale-indexed map, and the diagram makes visible which forced inputs leave that map with no room to branch.

The following diagram summarizes the five links:

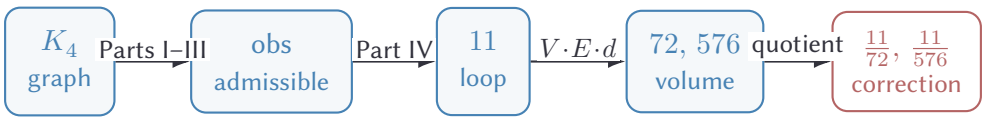

Figure 51.2: The correction chain. Each arrow is a canonical map forced by elimination.

Derived quantity	Bare	Numerator	Derived volume	Correction
Proton mass ratio	1836	11	$72 = V \cdot E \cdot d$	$+11/72$
Weinberg angle	0.25	11	$576 = V \cdot E \cdot d \cdot \kappa$	$-11/576$
Muon mass ratio	207	$16 = \kappa\chi$	$69 = d \cdot (E + F_2)$	$-16/69$
Tau/muon ratio	17	$28 = d^2 + F_2 + \chi$	$153 = d^2 \cdot F_2$	$-28/153$
α^{-1}	137	11	$306 = d \cdot E \cdot F_2$	$+11/306$
RG slope	—	1	$274 = 2\alpha^{-1}$	$1/274$
Baryon fraction	$1/6$	$1 = F_2 - 2^V$	$102 = E \cdot F_2$	$-1/102$

Proton and electroweak corrections share the same forced loop numerator 11 because the loop sector survives elimination only once and is then evaluated at two canonical volumes. The fine-structure correction reuses the same numerator 11, now at the coupling-compactification volume $d \cdot E \cdot F_2 = 306$. The tau correction uses the bridge numerator $d^2 + F_2 + \chi = 28$, forced by the three-filter chain proven in §51. The muon bridge $\kappa\chi = 16$ is forced by spinor saturation. The RG slope belongs to a different derived channel: its numerator is forced at 1 by the primality of $\alpha^{-1} = 137$ (§51), while its denominator $2\alpha^{-1} = 274$ is the canonical coupling volume. The baryon fraction correction extends the bare denominator $E = 6$ into the compactification channel: among $\{V, d, \chi, \kappa, F_2\}$, only $F_2 = 17$ is coprime to E, forcing the volume $E \cdot F_2 = 102$; the corrected numerator is the spinor dimension $2^V = 16$, so the correction $F_2 - 2^V = 1$ yields $-1/102$ and the corrected fraction $8/51$ (§51). In each case, the continuum correction is downstream of already fixed discrete data.

Classification of Derived Sectors

The preceding sections fixed the admissibility filter and the primitive observable basis. But the physics chapter does not end at that basis. It must still show how the derived sectors built from the ledger survive elimination. This section performs that harsher census: not of new primitive observables, but of the derived candidate spaces for coupling, mass, loop numerator, and correction volume. In each case the task is the same. A finite sector is exposed, weaker survivors are shattered, and exactly one derived quantity remains.

Classification of $\alpha^{-1} = 137$

The value $\alpha^{-1} = 137$ does not enter here as a chosen formula. By the stage at which it is classified, the construction is already closed in the only places where hidden freedom could have entered: the graph is fixed as K_4, the invariant ledger (V, E, d, χ, κ) is fixed, and the admissibility filter has already eliminated presentation-dependent, non-canonical, and proof-sensitive quantities. The remaining task is therefore not to pick a coupling value, but to expose the unique survivor in the derived coupling sector.

Constraint: The coupling value must remain inside the admissible derived sector determined by the earlier filter. Any candidate must be invariant under $\mathrm{Aut}(K_4)$, factor through the canonical invariant basis already fixed, and stay within the graph-forced local complexity bound. If one relaxes any of these conditions, the value is no longer derived from the surviving structure but from reintroduced representational slack.

Elimination: Classification first eliminates every single monomial in the invariant basis as a possible source of 137, then eliminates all degree-≤ 3 admissible two-term completions except one. Exactly one decomposition survives: $128 + 9 = V^3\chi + d^2 = V^2\kappa + d^2$.

Consequence: The value is not fitted to experiment and not selected by taste. It is the unique survivor of the admissibility constraints in the bounded derived coupling sector. Any alternative value would require either non-invariant structure, non-canonical observables, or restored representational freedom, and each of those has already been eliminated upstream.

The coupling constant $\alpha^{-1} = 137$ is prime. No single monomial in the K_4 invariants $\{V{=}4,\ E{=}6,\ d{=}3,\ \chi{=}2,\ \kappa{=}8\}$ of degree ≤ 3 evaluates to 137, because all such monomials factor through 2, 3, or both. The value is therefore not a coincidence of a single structural factor; it requires at least two terms.

Among all pairs (M_1, M_2) where each M_i is a monomial of degree ≤ 3 in the K_4 invariants, the decomposition $M_1 + M_2 = 137$ has exactly one solution: $128 + 9$. The first term $128 = V^3\chi = V^2\kappa$ combines spectral scaling with topology; the second term $9 = d^2$ is the geometric square of the vertex degree. No other pair of degree-≤ 3 monomials sums to 137.

Invariant-kind independence: why bulk and boundary add

The binomial decomposition $128 + 9$ is not a numerical coincidence; it is forced by a structural separation in the invariant algebra of K_4. The three invariants that build the coupling constant arise from three categorically disjoint origins: λ is a spectral invariant (Laplacian eigenvalue), χ is a topological invariant (Euler characteristic), and d is an algebraic invariant (vertex degree). No reduction path connects one kind to another within K_4: the spectral decomposition does not determine the Euler number, and neither determines the vertex degree. They are independent structural witnesses.

This independence has a sharp formal consequence. The bulk term $\lambda^3\chi = 128$ couples spectral and topological information; the boundary term $d^2 = 9$ carries purely algebraic information. Because these kinds are logically disjoint—different constructors of the same data type—the two terms constrain different structural dimensions of K_4. Independent constraints combine as coproducts in the categorical sense, and the forgetful functor maps coproducts to sums. The addition sign in $128 + 9$ is therefore not chosen; it is the image of invariant-kind disjointness under the passage from structure to number.

Constraint: The combination law for bulk and boundary must be determined by the structural relationship between the invariants involved, not by external convention.

Elimination: Suppose the combination were multiplicative: then bulk and boundary would act as simultaneous constraints on the same structural sector—but $\mathrm{spectral} \equiv \mathrm{algebraic}$ has no inhabitant, so no shared sector exists. Suppose the combination were any non-additive binary operation: it would require a structural coupling between kinds, which the disjointness of constructors prohibits. The type $\mathrm{InvariantKind}$ has exactly three constructors; the compiler verifies that no identification between them is derivable. Every non-additive combination law is thereby refuted.

Consequence: Only additive combination survives. The plus sign in $128 + 9 = 137$ is the last step of the elimination chain.

Degree bound and two-term necessity

The remaining laws explain why the search stops at degree three and why a single monomial cannot hit the prime value 137. This keeps the bound as a structural statement rather than a hidden search parameter.

The justification for the degree bound is structural, not merely numerical. One cannot simply say that every monomial of degree at least four already exceeds 137: that statement is false in raw arithmetic, since expressions such as $\chi^4 = 16$, $\chi^4 d = 48$, $\chi^4 E = 96$, and $\chi^4 V = 64$ remain below 137. The real point is different. The graph itself fixes the natural local complexity scale: K_4 has degree $d = 3$, and this same value appears as the simplex depth used in the coupling law. Monomials of degree at most three therefore exhaust the primitive local observables naturally generated by the graph's own interaction depth. Going beyond degree three does not reveal a new local layer of K_4; it merely iterates already available invariants into higher-order composites.

This matters for the epistemic status of the argument. At the standard set by the beginning of the book, elimination must always act on an explicitly delimited class of alternatives. That is exactly what happens here: the sector under classification is the class of primitive local observables on K_4, and the graph's own degree fixes that class at complexity ≤ 3. Within that class, the arithmetic classification becomes sharp. The only admissible two-term completion of the prime value 137 is $128 + 9 = V^3\chi + d^2$. Higher-degree terms are therefore not being ruled out as meaningless formal expressions in general; they are being ruled out from this particular elimination problem because they lie outside the primitive observable sector being classified.

This cutoff cannot remain a verbal convention. If the primitive sector were left implicit, the bound deg $\leq d$ could be mistaken for a search parameter chosen after 137 was already visible. The graph itself blocks that escape. The simplex depth is the local interaction depth of K_4, and Law 16B.5 identifies that depth with the graph degree. Primitive observables therefore stop exactly where iteration begins.

Constraint: The admissible local sector must be delimited by graph structure alone. A bound introduced only to hit 137 would destroy the elimination claim.

Elimination: Any monomial exceeding simplex-degree is eliminated from the primitive sector. Since $\text{simplex-degree} \equiv d$, the cutoff is read directly from K_4. A primitive observable is therefore represented by a monomial in the invariant basis $\{V, E, d, \chi, \kappa\}$ together with a proof that its total degree does not exceed this bound.

Consequence: Degree-4 terms such as χ^4 are not forbidden as expressions. They are classified as iterated composites outside the primitive sector. The α^{-1} decomposition survives this filter: $V^2\kappa$ has degree 3, and d^2 has degree 2.

A sharper question concerns the class itself. Why monomials? Why not expressions such as V^E or χ^d, where one invariant appears as the exponent of another? The question is answered by the type, not by taste. The record ObservableMonomial carries five fields exp-V, exp-E, exp-d, exp-χ, exp-κ of type $\mathbb{N}$. These are compile-time-constant natural numbers fixed when the monomial is specified; they are not variables determined at evaluation time by the values of other invariants. An expression V^E would require setting exp-V $= 6$—the numerical value of E—but then the relationship "exponent equals the value of E" has no representation in the type: exp-V is simply 6, not E. The parametric dependency is absent from the type system. Likewise χ^d: to place it in ObservableMonomial one would write exp-$\chi = 3$, with the coincidence "$3 = d$" as an external gloss not expressed in any field. That is not a choice against V^E and χ^d; it is the observation that those expressions have no term in Set. The monomial basis is the unique class that eval-monomial : ObservableMonomial $\to \mathbb{N}$ actually types.

The verbal claim that "no other pair of degree-≤ 3 monomials sums to 137" is now backed by exhaustive absurdity witnesses. Each field asserts that a specific pair-sum equals 137, and the proof $\lambda\ ()$ shows that the equality type is empty—the values are simply different natural numbers. This is pure elimination: twelve alternatives tested, twelve destroyed, one survivor.

Epistemic status

The classification results above establish the following census:

1. $\alpha^{-1} = 137$**: forced by elimination.** Once the graph, invariant ledger, and primitive cutoff are fixed, the coupling sector contains exactly one admissible survivor. Among all two-term degree-≤ 3 completions, only $V^d\chi + d^2 = 128 + 9$ reaches the prime value. No alternative passes the filter.

2. **Loop numerator** 11**: forced by elimination.** The loop sector is finite and explicit. Among all $\{0,1\}$-linear combinations of $\{E, d, \chi\}$, exactly one satisfies irreducibility (gcd $= 1$ with 72), completeness, and cross-scale consistency. The partial candidate $d + \chi = 5$ collapses on completeness. Only $E + d + \chi = 11$ survives.

3. **Denominators** 72**,** 576**,** 69**,** 153**,** 274**: derived;** 306**,** 102**: eliminated.** The first five are canonical products of quantities already forced upstream: $V{\cdot}E{\cdot}d$, $V{\cdot}E{\cdot}d{\cdot}\kappa$, $d{\cdot}(E{+}F_2)$, $d^2{\cdot}F_2$, $2\alpha^{-1}$. The sixth, $306 = d{\cdot}E{\cdot}F_2$, is the unique product of the factor pool surviving three filters that exclude V, κ, and χ from the coupling-correction volume (§51). The seventh, $102 = E{\cdot}F_2$, is forced because F_2 is the unique K_4 invariant coprime to the bare baryon denominator $E = 6$ (§51).

4. **Proton bare mass** 1836**: forced by elimination after reduction.** The mass sector separates compactification content from local graph content. The compactified spinor survivor is already fixed at $F_2 = 17$, and the remaining cofactor reduces through $\chi d = E$ to the primitive edge channel. There, among all degree-≤ 3 monomials in $\{E, d\}$, exactly one evaluates to 108, namely $E^2 d$. The full product $F_2 \cdot E^2 d = 1836$ is therefore forced.

5. **Muon bare mass** 207**: forced by elimination.** The muon sector survives only if its two channels remain distinct: geometric square and mixed compactification sum. Among the degree-only candidates $1, d, d^2, d^3$, exactly one evaluates to 9. Among the additive candidates $0, E, F_2, E + F_2$, exactly one evaluates to 23. Their product is therefore forced as $9 \cdot 23 = 207$.

6. **Muon bridge** $\kappa\chi = 16$**: forced by spinor saturation.** The bridge numerator must be coprime to both muon channels, free of F_2, and bounded by the spinor dimension $2^V = 16$. Of the four survivors $\{2, 4, 8, 16\}$, only $\kappa\chi = 16$ saturates the spinor bound. The three eliminated values carry only one side of the spectral-topological coupling.

7. **Tau/muon ratio** 17**: forced by compactification elimination.** The terminal ratio sits in the compactification channel itself. That channel carries only two candidates: the raw spinor count 16 and its one-point compactification 17. Only one survives the terminal value filter. The survivor is $F_2 = 17$.

8. **Tau bridge** $28 = d^2 + F_2 + \chi$**: forced by three-filter elimination.** Among the five candidate extensions of the tau base $d^2 + F_2$, two fail coprimality with the channel values and two exceed the sub-degree bound. The unique survivor is χ, yielding the correction $-28/153$ and matching the measured tau/muon ratio to 1.9×10^{-6}.

9. **Fine-structure correction** $+11/306$**: forced by three-filter elimination.** The coupling-correction denominator $d \cdot E \cdot F_2 = 306$ is the unique product of the surviving factor pool after excluding V (consumed in proton volume), κ (consumed in EW volume), and χ (enters bare coupling formula). The correction reuses the universal loop numerator 11 and matches α^{-1} to 3.8×10^{-7}.

10. **Coupling ratio $1/274$: forced by primality.** The unique irreducible fraction whose numerator divides $\alpha^{-1} = 137$ (prime) is $1/274$. The candidate $137/274$ fails irreducibility ($\gcd(137, 274) = 137$). The survivor $1/274$ is a K_4-combinatorial ratio; its interpretation as a physical coupling derivative is offered but not proved here.

11. **Baryon fraction $8/51$: forced by coprimality filter and spinor saturation.** The bare fraction $1/E = 1/6$ is corrected by extending the denominator into the compactification sector. Among $\{V, d, \chi, \kappa, F_2\}$, only $F_2 = 17$ is coprime to $E = 6$, forcing the volume 102. The corrected numerator is the spinor dimension $2^V = 16$; the correction numerator $F_2 - 2^V = 17 - 16 = 1$ is derived, not chosen. The corrected fraction $16/102 = 8/51 \approx 0.157$ matches Planck $\Omega_b/\Omega_m \approx 0.157$ to $\sim 0.1\%$.

The correction chain is closed for α^{-1}, for the loop numerator, for all seven correction fractions, and for the bare proton, muon, and tau sectors. What changes from one mass sector to the next is not the standard of proof, but the channel through which the surviving structure is allowed to speak. In the proton sector the graph first sheds its topological clothing and reveals an edge-channel core. In the muon sector the story splits into two visibly different motions: one geometric, one compactificatory, and the value survives only when those motions are kept separate until the end. In the tau sector even that split disappears: only the compactification residue is left on the table. None of these moves is an escape hatch. Each is forced by the way the graph freezes some degrees of freedom and leaves exactly one live channel behind.

Mass-sector admissibility sector

The proton value 1836 cannot be allowed to enter as a decorative product assembled after the fact. By the time the mass sector is reached, the same eliminative discipline that fixed α^{-1} is already in force here as well: new compactification content must be separated from local graph content, and whatever survives locally must survive inside an explicitly delimited admissibility sector. Physically, the reader should picture a two-stage filter. First, the genuinely new compactification content is isolated so that it cannot be smuggled back into local graph arithmetic. Then the local residue is forced to show its face inside the primitive channel already carved out by the graph. If that separation fails, the proton factorization collapses into bookkeeping.

What the graph leaves standing is a two-layer channel and nothing else. One layer contributes the genuinely new compactification survivor $F_2 = 17$. The other contributes a local cofactor that must already be present in the primitive observable sector once the topological route has been reduced through $\chi d = E$. In more concrete terms: one hand carries the compactification prime, the other hand carries the smallest local cofactor the graph cannot eliminate. The task is therefore not to decorate 1836 with factors, but to expose the only factorization that survives this split.

Constraint: The mass observable must separate genuinely new compactification content from local graph content. If these layers are mixed, the factorization ceases to be structural.

Elimination: Any factorization that blurs the boundary between compactification content

and local graph content is eliminated. The new factor $F_2 = \mathrm{suc}(\text{clifford-dimension})$ survives as the only coprime prime channel. The local cofactor sector consists of primitive monomials whose reduced value is the edge-channel cofactor $E^2 d = 108$. The higher-degree presentation $\chi^2 d^3$ is retained only as a derivable route into that reduced cofactor.

Consequence: The proton formula is no longer a floating product. It lies in an explicit admissibility sector: compactification prime times reduced primitive cofactor. Any rival factorization would have to blur this separation, reintroduce non-primitive local structure, or abandon the compactification channel already fixed upstream. The reduced cofactor is then classified exhaustively below.

Reduced edge-channel elimination

Reduction cannot stop at a slogan either. Once the cofactor has been pushed through $\chi d = E$, no hidden reservoir of alternatives remains. The surviving local channel is finite and exposed. There are only ten monomials in the edge channel $\{E, d\}$ of total degree at most three. If more than one of them hit 108, the proton cofactor would remain ambiguous. If exactly one survives, the ambiguity is shattered and the edge channel closes.

Constraint: The reduced cofactor must live in the primitive edge channel and remain within the graph-forced cutoff $\deg \leq d = 3$.

Elimination: Enumerate all degree-$\leq$ 3 edge-channel monomials, evaluate each on K_4, and eliminate every candidate except the unique survivor at value 108.

Consequence: E^2d is not a convenient rewrite of the cofactor. It is the only reduced primitive edge-channel monomial that survives the value filter. Every weaker alternative is eliminated inside the finite case space itself. The proton mass is therefore forced as $F_2 \cdot E^2d = 17 \cdot 108 = 1836$.

Muon mixed-channel elimination

The muon sector cannot be left at the level of a suggestive product either. Once the proton has been forced, the next pressure point is obvious: is $207 = d^2(E + F_2)$ equally unavoidable, or is this the first place where convenience re-enters? The graph blocks that escape by forcing another finite sector. This time the structure does not collapse into a single multiplicative channel immediately. Instead it visibly splits into two pieces that do different jobs. The geometric contribution measures pure local repetition along the degree axis. The compactification contribution measures the extra residue that appears only when the edge channel and the compactified spinor channel are allowed to meet additively. Both spaces are small enough to classify exhaustively, so nothing can hide behind informal plausibility.

Constraint: The muon observable must keep the local geometric square distinct from the compactification correction. Repeating either channel would double-count structure and destroy the decomposition.

Elimination: Enumerate the degree-only candidates $1, d, d^2, d^3$ and the mixed additive candidates $0, E, F_2, E + F_2$. Every candidate except one in each list is eliminated by the value filter. Exactly one candidate in the first list evaluates to 9, and exactly one in the second evaluates to 23.

Consequence: The product $d^2(E+F_2)$ is not a guess. It is the only product assembled from the unique geometric-square survivor and the unique mixed additive survivor. Any alternative muon factorization would have to alter one of those two finite survivor classes, and neither class has any room left. The muon bare mass is therefore forced as 207.

Tau compactification elimination

The tau sector is smaller, but it cannot be treated more loosely. Once the compactification channel has appeared in both proton and muon formulas, the terminal ratio $\tau/\mu = 17$ must survive by the same standard or the chain weakens at its end. Here the candidate space is minimal, and that is exactly why the section matters. All geometric clutter has already burned away. Nothing remains but the compactification channel itself: the raw spinor count and its one-point compactification. If both remained viable, the terminal ratio would still carry unresolved slack. If only one survives, the compactification channel closes without residue.

Constraint: The terminal lepton ratio must come entirely from the compactification channel, with no leftover geometric factor.

Elimination: Enumerate the two compactification candidates: the raw spinor count $\mathrm{Cl}(\mathbb{R}^4)$ dimension $= 16$, and its one-point compactification $F_2 = 17$. The raw spinor count fails the geometric-residue filter; the compactified value survives.

Consequence: The tau/muon ratio is not merely equal to F_2. It is the unique survivor of the compactification channel. The alternative value 16 is not approximately wrong or philosophically weaker; it is eliminated inside the only candidate space available. The terminal ratio is therefore forced as 17.

Physics Presupposes Distinction

The final asymmetry can no longer remain implicit. Up to this point the book has forced the physical record from the invariant spine of K_4. A weaker reader could still try to reverse the

dependence and say that physics is the deeper object, while K_4 is only one successful encoding of it. That escape collapses at the type level.

A physical record here is not a free-standing bag of measured numbers. It is threaded together by identity witnesses: the anchor tying dimension to K_4, the chain laws transporting that anchor through every other field, and the closure proofs showing that rival admissible records collapse to the same object. If identity is removed, these fields are not weakened. They become uninhabitable. Physics therefore does not generate distinction. It consumes the logical infrastructure distinction has already forced.

Constraint: An admissible physical record already contains equality data. The anchor and chain constraints of $\mathrm{K4PhysRep}$ presuppose the identity type, and the identity type presupposes the distinction-theoretic base established at the beginning of the book. If distinction were denied, the physics record would not become deeper; it would become uninhabitable.

Elimination: Extract the record's own equality witness and use it to eliminate the reversed-dependency hypothesis in two forms. First, every inhabitant of $\mathrm{K4PhysRep}$ yields a distinction witness—so physics cannot exist without distinction. Second, assuming $\neg$ *Distinction* annihilates every purported physical record, so physics without distinction collapses to $\bot$.

Consequence: The dependency arrow cannot be reversed. Physics is an invariant of K_4, but K_4 is not reconstructed from a prior physics layer. The physical record already lives inside the logical world distinction opened. Physics as fundament is therefore eliminated by self-presupposition.

This does not close the book by withdrawing from physics into logic. It closes the directional ambiguity that would otherwise remain at the threshold. The route from distinction to K_4 to the physical record is fixed in one direction only. What remains is not another internal theorem, but the outward question that this fixed direction leaves behind: what follows once physics has been shown to depend on distinction rather than ground it?

Chapter 52

The Invitation

The chain is closed in the only direction that survives scrutiny. Distinction forces the two-class carrier; the carrier forces K_4; K_4 forces the invariant ledger; and the admissible physical record is shown, in the end, to presuppose the very distinction from which the chain began. What remains is therefore not a request for lenience. It is a ledger of the surviving debts. The proof no longer waits for completion, but it does leave obligations behind: comparison with rival physical explanations, sharpening of the mathematical form, and a philosophical account of what kind of necessity has been uncovered.

The existence of D_0 itself—the claim that $\mathrm{Distinction}$ is inhabited—has been established by three independent routes, each eliminating a different escape. First, $\mathrm{Two\text{-}distinction}$ (Chapter 5) constructs a witness from pure type theory, with no assumptions whatsoever. Second, $\mathrm{measurement\text{-}outcome\text{-}distinction}$ (Chapter 50) extracts a distinction from any binary measurement apparatus: the yes/no separation that measurement presupposes is already one. Third, $\mathrm{physics\text{-}presupposes\text{-}distinction}$ closes the loop from the other end: every admissible K_4 physical record already consumes the distinction it claims to ground. No single route can be dismissed without abandoning a different foundational commitment—constructive logic, empirical content, or physical admissibility, respectively.

The invitation is the place where those debts are named without reopening the chain. It states, for each audience in turn, where resistance is still possible, where the real pressure falls, and what kind of response would count as serious.

To Physicists

This manuscript does not ask for deference to formalism, and it does not claim a new empire of prediction. It makes a narrower and harsher claim. Starting from distinction, and permitting only structures that survive explicit elimination, one is driven to a graph, to an invariant ledger, and then to a small cluster of computed quantities that can be compared with physics. Those comparisons are on the table in their final form.

After the last asymmetry has been made explicit, the central physical question is no longer whether physics secretly grounds the chain. That path has been closed. The live question is

whether the surviving match to measured structure is accidental, derivative, or telling us something real about how much of physics is already fixed before phenomenology begins.

If the match is accidental, the standard of reply is clear. One must produce another structure with comparable rigidity and no hidden freedom that reaches the same constants with equal precision. If the match is not accidental, the burden changes. One must explain why elimination on such a small discrete spine reaches as far into the measured world as it does.

The physical debt is therefore comparative rather than decorative. The chain is not asking for applause. It is asking whether any equally rigid route reaches the same measured structure, or whether this one is already telling us that more of physics is fixed before model-building begins than the usual story admits.

To Mathematicians

The formal chain is closed, but closure is not the same as exhaustion. What survives here is strong enough to be interrogated from several directions at once: proof-theoretic, categorical, spectral, and geometric. The invitation is therefore not to repair a missing proof, but to decide whether the surviving structure admits a sharper and more illuminating formulation.

Several pressure points are immediate:

- K_4 uniqueness is proven by exhaustive classification (theorem-4-unique-fixpoint). The endomorphism classification already constitutes a representability theorem: $\mathrm{End}(S\,d) \cong \mathrm{EndoCase}$ for all distinctions d (theorem-endo-representability). Can this be lifted to a topos-theoretic or sheaf-theoretic statement that characterizes K_4 without exhaustive case analysis?

- The fold establishes algebraic stability for finite lattices. Can category theory (e.g. topos-theoretic methods) extend this to a sheaf-theoretic statement?

- The drift hierarchy is a strict total order (theorem-drift-strict-total-order). Its ordinal type is asserted to be ω in the prose. Can an explicit ordinal isomorphism $\mathrm{DriftState} \cong \omega$ be constructed under --safe, given that Agda's Level is opaque?

- What is the relationship between the drift operad and existing operadic structures in mathematical physics (e.g. Kontsevich formality)?

The mathematics is self-contained. The open work is not to rescue the argument from incompleteness, but to determine whether the same survivor can be characterized in a form that is even more rigid, more general, or more transparent.

This is the largest technical debt left by the manuscript. The theorem chain stands, but its strongest surviving form may still be ahead of us: a presentation in which classification becomes inevitability in an even sharper sense than exhaustive proof can display.

To Philosophers

Every epoch produces a new observer and a new key to intelligibility. One age trusts geometry. Another trusts experiment. Another trusts symmetry, or information, or computation. This work belongs to a later observer: one who asks what remains when every explanatory surplus is forced to justify itself and only formal survival is allowed to stay.

That shift matters. The manuscript does not begin from world, mind, or measurement and then ascend toward abstraction. It begins from the bare fact of distinction and asks what can survive collapse. If physical structure reappears at the end of that descent, then the philosophical problem is no longer how mathematics is applied from outside. It is how far the order of the world is already exposed by the conditions of stable form.

- If physical constants are determined by logic, what does this say about the nature of physical law?
- What is the ontological status of a mathematical structure that computes the parameters of the universe?
- What becomes of scientific realism if successive traditions are not competitors but partial witnesses of the same invariant order?

The philosophical debt is therefore neither ornament nor rescue. It is to say what has happened when a structure reached by elimination behaves less like a formal toy and more like an exposed layer of the world. If that question is avoided, the proof remains intact, but its meaning is left underdescribed.

Taken together, these are the debts that survive the end of the proof: empirical comparison, mathematical sharpening, and philosophical interpretation. None of them reopens the chain from distinction to K_4 to the physical record. They begin only after that chain has been forced. The conclusion therefore does not add one more theorem. It names what kind of survivor has been left in our hands.

Chapter 53

Conclusion

We began with a mark on a blank page—the simplest possible act: separating something from nothing. Nothing in the chain that followed was allowed to stand by taste, elegance, or convenience. The question was harsher from the beginning: what remains if every unstable alternative is forced to fall away?

By the end, even the final temptation to reverse the chain had been eliminated. The physical record did not stand behind distinction as a deeper source from which K_4 could be rebuilt. It stood downstream, already inhabiting the equality and distinction structure it might have claimed to explain. The dependence ran one way only.

Through the entire chain, the method stayed the same. Not invention, but elimination. Not ornament, but survival. Equality had to survive. Negation had to survive. Classification had to survive. Reachability, presentation, fixpoint, graph, arithmetic, spectrum, observable: each was admitted only where contradiction failed to destroy it.

What survived was small. A distinction. Two sides. Four cases. One graph. A narrow arithmetic. A rigid spectrum. A short list of invariants. That is why the result is unsettling. It does not arrive as a grand architecture chosen for elegance. It arrives as residue.

No triumph should be claimed here. This work does not say that the physicists were wrong and the logicians were right, or that the mathematicians were early and the philosophers confused. It says something more difficult: that they may all have been watching the same constraint from different entrances.

Each epoch brings forth a new observer and a new key to knowledge. One measures. One classifies. One formalizes. One asks what symmetry will allow. One asks what computation will certify. This book belongs to that last lineage. It asks a single question and refuses to relax it: what if nothing remains except distinction, consistency, invariance, and the structures they force?

Then almost everything disappears.

No new empire of prediction is announced here. No license is claimed to outrank experiment. The modest claim is the stronger one: we do not need to show more than that the great observations and achievements of their respective traditions may be locally right together. Brouwer's witness, Martin-Löf's discipline, Euler's count, Cayley's symmetry, Noether's invari-

ance, Curie's asymmetry, Dirac's severity, Feynman's consistency of paths—none is overturned here. They survive.

What now survives with them is a threefold obligation. The empirical question is comparative: whether any equally rigid route reaches the same measured structure without concealed freedom. The mathematical question is sharpening: whether the survivor can be recast in a form still more inevitable than exhaustive classification. The philosophical question is interpretive: what kind of necessity has been exposed if a structure forced by elimination reaches so far into the world we measure.

If this manuscript has earned any right to continue beyond its last code line, it is because it leaves us with a cleaner question than the one with which it began. Why should the survivor of formal elimination resemble the measured world at all? Why should a structure forced by logic meet the constants of physics where they are sharpest?

Those are not repairs to a broken argument. They are the proper debts of one that has reached its limit without collapsing. The proof ends where comparison, sharpening, and interpretation begin.

That is not a failure of the book. It is the honest end of the journey.

The code stops here. The investigation does not.

Quod erat demonstrandum.
